A THERAPEUTIC STEP AHEAD

LOPID®
(gemfibrozil)

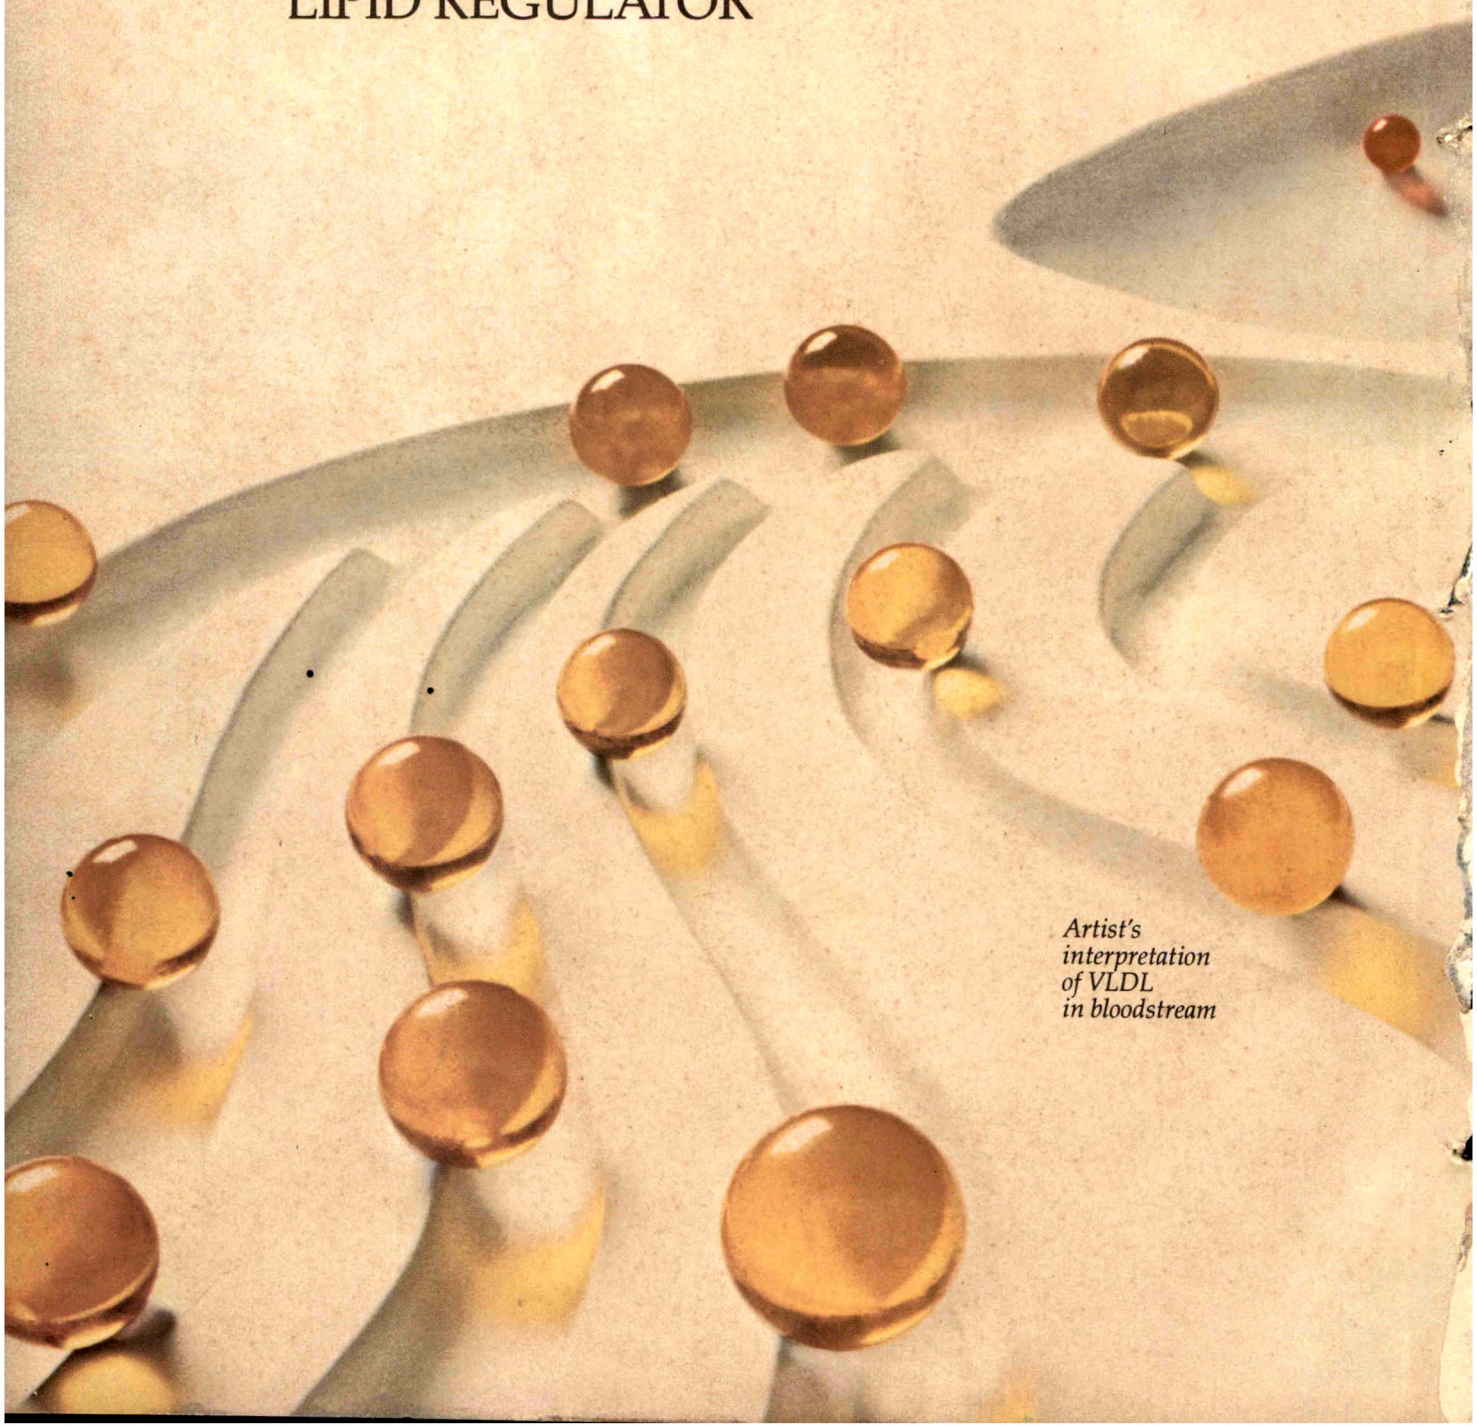
MORE THAN A LIPID-LOWERING AGENT— A TWO-WAY LIPID REGULATOR

Favorably regulates the balance of lipid fractions in certain dyslipidemias:

1/LOWERS elevated serum levels of triglyceride-rich VLDL and, to a lesser extent, cholesterol-rich LDL (very-low- and low-density lipoproteins implicated in dyslipidemia)

2/May also RAISE serum levels of HDL (high-density lipoproteins believed to transport cholesterol to the liver for catabolism and excretion)

LOPID is indicated for treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of pancreatitis and who do not respond adequately to diet.

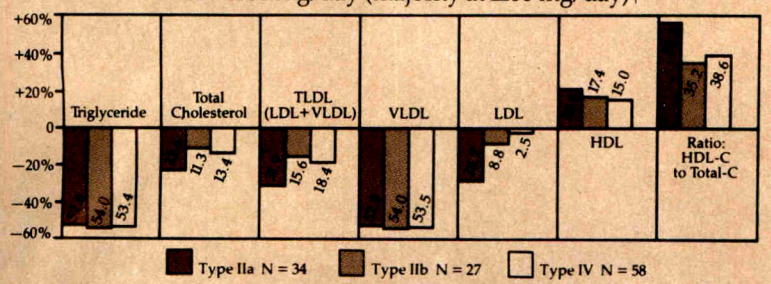


Artist's interpretation of VLDL in bloodstream

Lipid-regulating efficacy demonstrated in 1,437 patients with dyslipidemia[1]

Results of open-label phase of US multicenter study (119 patients) at end of 12 lunar months*

Average % change from baseline at doses ranging from 800-1600 mg/day (majority at 1200 mg/day)†



*Visit every 4 weeks during long-term use of LOPID.

†Data cited on this graph reflect clinical experience based on the multicenter trial. They do not imply an indication for Types IIa and IIb dyslipidemias.

Well tolerated, well accepted in clinical trials[1]

Profile of side effects similar to that of placebo.

No significant abnormalities seen in clinical and laboratory evaluations.

Less than 1% patient dropout in largest US study.

Convenient BID dosage

Diet, exercise, and weight loss are the first choice in therapy of lipid disorders.

LOPID® (gemfibrozil)
A LIPID REGULATOR

LOPID® (gemfibrozil) Capsules

Before prescribing, please see full prescribing information.
A Brief Summary follows:

CLINICAL PHARMACOLOGY. LOPID is a lipid regulating agent which lowers elevated serum lipids primarily by decreasing serum triglyceride with a variable reduction in total serum cholesterol. These decreases occur primarily in the very low density lipoprotein (VLDL) fraction and less frequently in the low density lipoprotein (LDL) fraction. In addition, LOPID may increase the high density lipoprotein (HDL) cholesterol fraction, an action considered of possible benefit to inhibition of the atherosclerotic process.

The mechanism of action has not been definitively established. In man, LOPID has been shown to inhibit peripheral lipolysis and to decrease the hepatic extraction of free fatty acids, thus reducing hepatic triglyceride production. LOPID also inhibits synthesis of VLDL carrier apoprotein, leading to a decrease in VLDL production.

Animal studies suggest that LOPID may, in addition to elevating HDL cholesterol, reduce incorporation of long-chain fatty acids into newly formed triglycerides, accelerate turnover and removal of cholesterol from the liver, and increase excretion of cholesterol in the feces.

LOPID is well absorbed from the gastrointestinal tract after oral administration. Peak plasma levels occur in one to two hours with a plasma half-life of 1.5 hours following single doses and 1.3 hours following multiple doses. Plasma levels appear proportional to dose and do not demonstrate accumulation across time following multiple doses.

LOPID mainly undergoes oxidation of a ring methyl group to successively form a hydroxymethyl and a carboxyl metabolite. Approximately seventy percent of the administered human dose is excreted in the urine, primarily as unchanged gemfibrozil. Six percent of the dose is accounted for in the feces.

In a large, controlled multicenter trial of 427 patients, lipid and lipoprotein changes from average baseline (%) by hyperlipoproteinemic (HLP) type are summarized below for those patients receiving gemfibrozil, 1200 mg/day, at the end of 12 weeks.

HLP Type	TRIGLYCERIDE	CHOLESTEROL				RATIO: HDL Cholesterol / Total Cholesterol
		Total	VLDL	LDL	HDL	
IIa	−44%	−4.2%	−44.3%	−5.8%	+24.6%	+33%
IIb	−45%	−8.6%	−45.0%	−6.4%	+19.5%	+34%
IV	−40%	−1.8%	−40.8%	+14.6%	+17.4%	+23%

INDICATIONS AND USAGE. Drug therapy should not be used for the routine treatment of elevated blood lipids for the prevention of coronary heart disease. Dietary therapy specific for the type of hyperlipidemia is the initial treatment of choice. Excess body weight and excess alcoholic intake may be important factors in hypertriglyceridemia and should be addressed prior to any drug therapy. Physical exercise can be an important ancillary measure. Contributory diseases such as hypothyroidism or diabetes mellitus should be looked for and adequately treated. The use of drugs should be considered only when reasonable attempts have been made to obtain satisfactory results with nondrug methods. If the decision is to use drugs, the patient should be instructed that this does not reduce the importance of adhering to diet.

Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, and the adverse findings with clofibrate in two large clinical studies (see Warnings), use of gemfibrozil should be restricted to the following indications.

LOPID may be considered for the treatment of adult patients with very high serum triglyceride levels (type IV hyperlipidemia) who present a risk of abdominal pain and pancreatitis and who do not respond adequately to a determined dietary effort to control them. Patients with triglyceride levels in excess of 750 mg per deciliter are likely to present such risk.

LOPID (gemfibrozil) has little effect on elevated cholesterol levels in most subjects. A minority of subjects show a more pronounced response. However, it must be understood that there is no evidence that use of any lipid-altering drug will be beneficial in preventing death from coronary heart disease (See WARNINGS). Therefore, the physician should be very selective and confine gemfibrozil treatment to patients with clearly defined risk due to severe hypercholesterolemia (eg, individuals with familial hypercholesterolemia starting in childhood) who inadequately respond to appropriate diet and more effective cholesterol-lowering drugs.

LOPID is not useful for the hypertriglyceridemia of Type I hyperlipidemia.

The biochemical response to gemfibrozil is variable, and it is not always possible to predict from the lipoprotein type or other factors which patients will obtain favorable results. It is essential that lipid levels be assessed and that the drug be discontinued after three months in any patient in whom lipids do not show significant improvement.

The effect of drug-induced reduction of serum cholesterol or triglyceride levels or elevation of HDL cholesterol levels on morbidity or mortality due to coronary heart disease has not been established. Several years may be required before ongoing long-term investigations will resolve this question.

CONTRAINDICATIONS. 1. Hepatic or severe renal dysfunction, including primary biliary cirrhosis.

2. Preexisting gallbladder disease. (See Warnings).

3. Hypersensitivity to gemfibrozil.

WARNINGS. 1. Because of chemical, pharmacological, and clinical similarities between gemfibrozil and clofibrate, the adverse findings with clofibrate in two large clinical studies may also apply to gemfibrozil. In the first of those studies, the Coronary Drug Project, 1000 subjects with previous myocardial infarction were treated for five years with clofibrate. There was no difference in mortality between the clofibrate-treated subjects and 3000 placebo-treated subjects, but twice as many clofibrate-treated subjects developed cholelithiasis and cholecystitis requiring surgery. In the other study, conducted by the World Health Organization, 5000 subjects without known coronary heart disease were treated with clofibrate for five years and followed one year beyond. There was a statistically significant 36% higher total mortality in the clofibrate-treated than in a comparable placebo-treated control group. The excess mortality was due to noncardiovascular causes, including malignancy, postcholecystectomy complications, and pancreatitis. The higher risk of clofibrate-treated subjects for gallbladder disease was confirmed.

2. Long-Term Toxicity and Animal Tumorigenicity Studies: Long-term studies have been conducted in rats and mice at one and ten times the human dose. The incidence of benign liver nodules and liver carcinomas was significantly increased in high dose male rats. The incidence of liver carcinomas increased also in low dose males, but this increase was not statistically significant (p greater than 0.05). There were no statistically significant differences from controls in the incidence of liver tumors in female rats, and in male and female mice.

Electron microscopy studies have demonstrated a florid hepatic peroxisome proliferation following LOPID administration to the male rat. Similar changes have not been found in the human liver.

Male rats had a dose-related increase of benign Leydig cell tumors. Subcapsular bilateral cataracts occurred in 10%, and unilateral in 6.3% of the high dose males.

3. Since a reduction of mortality from coronary artery disease has not been demonstrated and liver and interstitial cell testicular tumors were increased in male rats, LOPID should be administered only to those patients described in the Indications and Usage Section. If a significant serum lipid response is not obtained, LOPID should be discontinued.

4. Cholelithiasis—LOPID may increase cholesterol excretion into the bile leading to cholelithiasis. If cholelithiasis is suspected gallbladder studies are indicated. LOPID therapy should be discontinued if gallstones are found.

5. Concomitant Anticoagulants—Caution should be exercised when anticoagulants are given in conjunction with LOPID. The dosage of the anticoagulant should be reduced to maintain the prothrombin time at the desired level to prevent bleeding complications. Frequent prothrombin determinations are advisable until it has been definitely determined that the prothrombin level has stabilized.

PRECAUTIONS. 1. **Initial Therapy**—Before instituting LOPID (gemfibrozil) therapy, every attempt should be made to control serum lipids with appropriate diet, exercise, weight loss in obese patients, and other medical problems such as diabetes mellitus and hypothyroidism.

2. **Continued Therapy**—Pretreatment laboratory studies should be performed to ensure that patients have abnormal levels of serum lipids. Periodic determinations of serum lipids should be obtained during LOPID administration. The drug should be withdrawn after three months if the lipid response is inadequate.

3. **Seasonal Variation of Lipid Levels**—LOPID is not expected to alter seasonal variations of higher serum lipid values in mid-winter and late summer or the lower values in fall and spring.

4. **Impairment of Fertility**—Administration of approximately three and ten times the human dose to male rats for 10 weeks resulted in a dose-related decrease of fertility. Subsequent studies demonstrated that this effect was reversed after a drug-free period of about eight weeks, and it was not transmitted to their offspring.

5. **Pregnancy Category B**—Reproduction studies have been performed in the rat at doses 3 and 9 times the human dose, and in the rabbit at 2 and 6.7 times the human dose. These studies have revealed no evidence of impaired fertility in females or harm to the fetus due to LOPID. Minor fetotoxicity was manifested by reduced birth rates observed at the high dose levels. No significant malformations were found among almost 400 offspring from 36 litters of rats and 100 fetuses from 22 litters of rabbits.

There are no studies in pregnant women. In view of the fact that LOPID is tumorigenic in male rats, the use of LOPID in pregnancy should be reserved for those patients where the benefit clearly outweighs the possible risk to the patient or fetus.

6. **Nursing Mothers**—Because of the potential for tumorigenicity shown for gemfibrozil in male rats, a decision should be made whether to discontinue nursing or discontinue the drug, taking into account the importance of the drug to the mother.

7. **Hematologic Changes**—Mild hemoglobin, hematocrit and white blood cell decreases have been observed in occasional patients following initiation of LOPID therapy. However, these levels stabilize during long-term administration. Therefore, periodic blood counts are recommended during the first 12 months of LOPID administration.

8. **Liver Function**—Abnormal liver function tests have been observed occasionally during LOPID administration, including elevations of SGOT, SGPT, LDH, and alkaline phosphatase. These are usually reversible when LOPID is discontinued. Therefore periodic liver function studies are recommended and LOPID therapy should be terminated if abnormalities persist.

9. **Cardiac Arrhythmias**—Although no clinically significant abnormalities occurred that could be attributed to LOPID, the possibility exists that such abnormalities may occur.

10. **Use in Children**—Safety and efficacy in children have not been established.

ADVERSE REACTIONS. In controlled clinical trials of 805 patients, including 245 who received LOPID for at least one year, the most frequently reported adverse reactions associated with LOPID involved the gastrointestinal system. In decreasing order of frequency, these were abdominal pain (6.0%), epigastric pain (4.9%), diarrhea (4.8%), nausea (4.0%), vomiting (1.6%), and flatulence (1.1%). Other adverse reactions where the probability of a causal relationship to LOPID therapy exists are listed by system.

Integumentary: rash, dermatitis, pruritus, urticaria

Central Nervous System: headache, dizziness, blurred vision

Musculoskeletal: painful extremities

Hematopoietic: anemia, eosinophilia, leukopenia

Other reactions have been reported under conditions where a causal relationship is difficult to establish, thus the physician should be alert to these occurrences. Reports of viral and bacterial infections (common cold, cough, and urinary tract infections) were more common in gemfibrozil than in placebo-treated patients.

Other reactions were:

Gastrointestinal: dry mouth, constipation, anorexia, gas pain, dyspepsia

Musculoskeletal: back pain, arthralgia, muscle cramps, myalgia, swollen joints

Central Nervous System: vertigo, insomnia, paresthesia, tinnitus

Clinical Laboratory: hypokalemia, liver function abnormalities (increased SGOT, SGPT, LDH, CPK, alkaline phosphatase)

Miscellaneous: fatigue, malaise, syncope

DOSAGE AND ADMINISTRATION. The recommended dose for adults is 1200 mg administered in two divided doses 30 minutes before the morning and evening meal. Some patients will experience therapeutic effects on 900 mg/day; a few may require 1500 mg/day for satisfactory results.

DRUG INTERACTIONS. CAUTION SHOULD BE EXERCISED WHEN ANTICOAGULANTS ARE GIVEN IN CONJUNCTION WITH LOPID (GEMFIBROZIL). THE DOSAGE OF THE ANTICOAGULANT SHOULD BE REDUCED TO MAINTAIN THE PROTHROMBIN TIME AT THE DESIRED LEVEL TO PREVENT BLEEDING COMPLICATIONS. FREQUENT PROTHROMBIN DETERMINATIONS ARE ADVISABLE UNTIL IT HAS BEEN DEFINITELY DETERMINED THAT THE PROTHROMBIN LEVEL HAS STABILIZED.

MANAGEMENT OF OVERDOSAGE. While there has been no reported case of overdosage, symptomatic supportive measures should be taken should it occur.

The Summary: The Manuscript's Bottom Line

Through the years I have asked numerous readers of medical journals which journal they read monthly and how they select which articles to read in a particular journal. The responses to the latter question indicate that the most frequent portion of a manuscript read is the manuscript's title, and next the manuscript's summary. If the latter is unappealing, most readers do not pursue other portions of the manuscript. But is the summary given the same attention by the author as it is given by the reader? I think not.

When writing medical papers with young associates, rarely have I been presented with a rough draft of a manuscript containing a summary. The summary, I suspect, tends to be written by many authors just before the final typing of the manuscript. Thus, when written last, the summary tends to be disjointed as it attempts to tie together the important points of the paper. When written first, the summary serves as an outline, focusing the thrust of the manuscript. Moreover, by being done last, the summary may not receive the thoughtful deliberation given other portions of the manuscript.

Because the summary is so important to a manuscript, I suggest that an author write this portion *first* (after the title) rather than last. By so doing, one may focus better on the number of points the particular manuscript is trying to make. If the manuscript has essentially only 1 point, the summary can be particularly crisp and short; if more than 1 point, the summary provides an outline of the points to be made. After the point or points of the manuscript are clearly in focus, the remainder of the paper can more readily build the case demonstrating the validity of each point. The summary then needs to be given the same emphasis and importance by authors as it receives from readers.

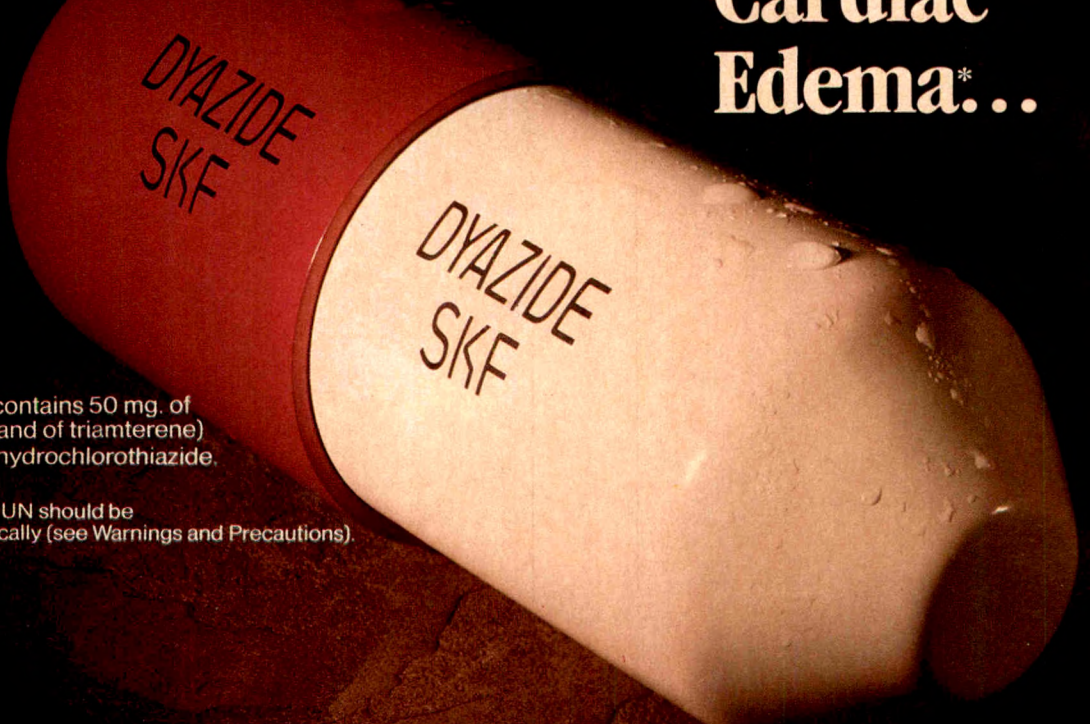
UNIVERSITY MED. CTR. LIBRARY

In Cardiac Edema*...



Each capsule contains 50 mg. of Dyrenium® (brand of triamterene) and 25 mg. of hydrochlorothiazide.

Serum K^+ and BUN should be checked periodically (see Warnings and Precautions).

When You Need to Conserve K+

Over 17 Years of Confidence

Before prescribing, see complete prescribing information in SK&F CO. literature or *PDR*. The following is a brief summary.

WARNING

This drug is not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual. If this combination represents the dosage so determined, its use may be more convenient in patient management. Treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Concomitant use with other potassium-sparing agents such as spironolactone or amiloride. Further use in anuria, progressive renal or hepatic dysfunction, hyperkalemia. Pre-existing elevated serum potassium. Hypersensitivity to either component or other sulfonamide-derived drugs.

Warnings: Do not use potassium supplements, dietary or otherwise, unless hypokalemia develops or dietary intake of potassium is markedly impaired. If supplementary potassium is needed, potassium tablets should not be used. Hyperkalemia can occur, and has been associated with cardiac irregularities. It is more likely in the severely ill, with urine volume less than one liter/day, the elderly and diabetics with suspected or confirmed renal insufficiency. Periodically, serum K^+ levels should be determined. If hyperkalemia develops, substitute a thiazide alone, restrict K^+ intake. **Associated widened QRS complex or arrhythmia requires prompt additional therapy.** Thiazides cross the placental barrier and appear in cord blood. Use in pregnancy requires weighing anticipated benefits against possible hazards, including fetal or neonatal jaundice, thrombocytopenia, other adverse reactions seen in adults. Thiazides appear and triamterene may appear in breast milk. If their use is essential, the patient should stop nursing. Adequate information on use in children is not available. Sensitivity reactions may occur in patients with or without a history of allergy or bronchial asthma. Possible exacerbation or activation of systemic lupus erythematosus has been reported with thiazide diuretics.

Precautions: Do periodic serum electrolyte determinations (particularly important in patients vomiting excessively or receiving parenteral fluids, and during concurrent use with amphotericin B or corticosteroids or corticotropin [ACTH]). Periodic BUN and serum creatinine determinations should be made, especially in the elderly, diabetics or those with suspected or confirmed renal insufficiency. Cumulative effects of the drug may develop in patients with impaired renal function. Thiazides should be used with caution in patients with impaired hepatic function. They can precipitate coma in patients with severe liver disease. Observe regularly for possible blood dyscrasias, liver damage, other idiosyncratic reactions. Blood dyscrasias have been reported in patients receiving triamterene, and leukopenia, thrombocytopenia, agranulocytosis, and aplastic and hemolytic anemia have been reported with thiazides. Thiazides may cause manifestation of latent diabetes mellitus. The effects of oral anticoagulants may be decreased when used concurrently with hydrochlorothiazide; dosage adjustments may be necessary. Clinically insignificant reductions in arterial responsiveness to norepinephrine have been reported. Thiazides have also been shown to increase the paralyzing effect of nondepolarizing muscle relaxants such as tubocurarine. Triamterene is a weak folic acid antagonist. Do periodic blood studies in cirrhotics with splenomegaly. Antihypertensive effects may be enhanced in post-sympathectomy patients. Use cautiously in surgical patients. Triamterene has been found in renal stones in association with the other usual calculus components. Therefore, 'Dyazide' should be used with caution in patients with histories of stone formation. A few occurrences of acute renal failure have been reported in patients on 'Dyazide' when treated with indomethacin. Therefore, caution is advised in administering nonsteroidal anti-inflammatory agents with 'Dyazide'. The following may occur: transient elevated BUN or creatinine or both; hyperglycemia and glycosuria (diabetic insulin requirements may be altered); hyperuricemia and gout; digitalis intoxication (in hypokalemia); decreasing alkali reserve with possible metabolic acidosis. 'Dyazide' interferes with fluorescent measurement of quinidine. Hypokalemia is uncommon with 'Dyazide', but should it develop, corrective measures should be taken such as potassium supplementation or increased dietary intake of potassium-rich foods. Corrective measures should be instituted cautiously and serum potassium levels determined. Discontinue corrective measures and 'Dyazide' should laboratory values reveal elevated serum potassium. Chloride deficit may occur as well as dilutional hyponatremia. Concurrent use with chlorpropamide may increase the risk of severe hyponatremia. Serum PBI levels may decrease without signs of thyroid disturbance. Calcium excretion is decreased by thiazides. 'Dyazide' should be withdrawn before conducting tests for parathyroid function.

Thiazides may add to or potentiate the action of other antihypertensive drugs.

Diuretics reduce renal clearance of lithium and increase the risk of lithium toxicity.

Adverse Reactions: Muscle cramps, weakness, dizziness, headache, dry mouth, anaphylaxis, rash, urticaria, photosensitivity, purpura, other dermatological conditions, nausea and vomiting, diarrhea, constipation, other gastrointestinal disturbances, postural hypotension (may be aggravated by alcohol, barbiturates, or narcotics). Necrotizing vasculitis, paresthesias, icterus, pancreatitis, xanthopsia and respiratory distress including pneumonitis and pulmonary edema, transient blurred vision, sialadenitis, and vertigo have occurred with thiazides alone. Triamterene has been found in renal stones in association with other usual calculus components. Rare incidents of acute interstitial nephritis have been reported. Impotence has been reported in a few patients on 'Dyazide', although a causal relationship has not been established.

Supplied: 'Dyazide' is supplied in bottles of 1000 capsules; Single Unit Packages (unit-dose) of 100 (intended for institutional use only); in Patient-Pak™ unit-of-use bottles of 100.

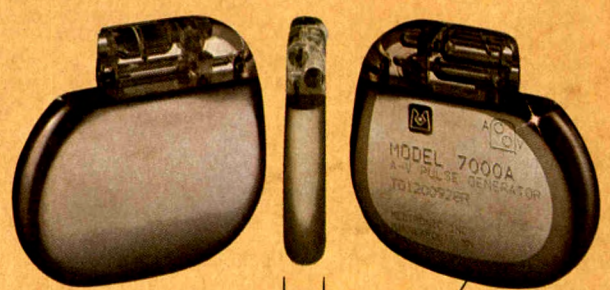
New VERSATRAX II

	340 ms.	A-V Sequential Pacing following a PVC...	235 ms.
THE FEATURE:	Atrial Refractory 340 ms. after a PVC...		Automatic Atrial Refractory adjusts to 235 ms. during A-V synchrony...
PATIENT BENEFIT:	To block sensing of retrograde when your patient needs it most	To restore synchrony	To track rapid atrial rates

Keeps a heart beating like a heart.

The most physiologic pacemaker.



52 grams 10mm Anti-muscle-stimulation coating

New Versatrax II Model 7000A is:

- **Automatic Atrial Refractory**
  The advanced physiological method of tracking the atrium and discriminating retrograde
- **Smallest**
  The most physiological size and shape available
- **Superior Sensing Performance**
  Medtronic's exclusive patented circuitry rejects most myopotentials
- **Plus... uniquely from Medtronic**
  - A-V Pacing System Analyzer—Model 5311
  - Endocardial screw-in leads—Models 6957/6957J
  - Follow-up choices—Cardiocare™/Teletrace™
  - Educational programs
  - Service options
  - Proven reliability

A-V Pacemaker

Intended Use

The Model 7000A universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing where restoration of A-V synchrony and/or sinus modulated rate variability is indicated to improve cardiac output or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

With the Model 7000A programmed in the A-V universal (DDD) mode, indications may include:

- Some of the sick sinus syndrome conditions such as intermittent sinus bradycardia, sinus arrest or SA block.
- Intermittent or complete atrioventricular block with normal sinus activity.
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V interval settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

In the A-V sequential (DVI) mode, the Model 7000A may have application in the following:

- Sick Sinus Syndrome (sinus bradycardia, sinus arrest, SA block, and the brady-tachy syndrome).
- Symptomatic bradycardia.
- Certain drug-resistant and reentrant tachycardias. (Short A-V delay settings may be useful in controlling some reentrant tachycardias.)
- Atrial and ventricular ectopic arrhythmias.

At any time, the Model 7000A can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 7000A universal A-V pulse generator is under clinical investigation in the U.S. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Uses" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 7000A pulse generator during its clinical investigation. Patients should be advised that the Model 7000A pulse generator is under clinical investigation.

Contraindications

General: There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician.

DDD Mode: The DDD mode is contraindicated in the presence of atrial fibrillation, atrial flutter and rapid atrial rhythms or slow retrograde conduction.

DVI Mode: In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation or flutter.

Warnings

Diathermy: Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site.

Electrosurgical Units: Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead.

Defibrillation: Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator. Positioning a magnet or the programming head over the pulse generator makes it subject to programming. A nominal vertical magnetic field strength of 90 Gauss (in a field measured 1½ inches from the magnet's surface) from a magnet at 1¼ inches from the reed switch is required to initiate asynchronous pacing. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programming head has been positioned over the pulse generator. If an electrocautery unit is used, the physician may prefer to program the pacemaker to asynchronous pacing prior to the procedure.

Precautions

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

Side Effects

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

CONTENTS IN BRIEF

JULY 1983 • VOLUME 52 • NUMBER 1

A note from the Editor-in-Chief, William C. Roberts, MD, appears on page A3 of this issue.

Coming July 20th: Symposium from The National Heart Foundation of Australia—the Physiology and Pathology of the Coronary Circulation and Coronary Heart Disease

CORONARY HEART DISEASE

1 **Intracoronary Thrombus in Nontransmural Myocardial Infarction and in Unstable Angina Pectoris.** Jay B. Mandelkorn, Nelson M. Wolf, Surender Singh, Jay A. Schechter, Robert I. Kersh, David M. Rodgers, Mark B. Workman, Lamberto G. Bentivoglio, Steven M. LaPorte, and Steven G. Meister, *With the technical assistance of* Barbara Tucker

7 **Comparison of High-Dose and Medium-Dose Propranolol in the Relief of Exercise-Induced Myocardial Ischemia.** Kenneth G. Morris, Michael B. Higginbotham, R. Edward Coleman, David G. Shand, and Frederick R. Cobb

14 **Anatomic and Prognostic Significance of New T-Wave Inversion in Unstable Angina.** David E. Haines, Daniel S. Raabe, Walter D. Gundel, and Frans J. Th. Wackers

19 **Ventricular Tachyarrhythmias in Prinzmetal's Variant Angina: Clinical Significance and Relation to the Degree and Time Course of S-T Segment Elevation.** Mario Previtali, Catherine Klersy, Jorge A. Salerno, Marcello Chimienti, Claudio Panciroli, Egidio Marangoni, Giuseppe Specchia, Mario Comolli, and Piero Bobba

26 **Long-Term Responses to Nifedipine in Patients With Coronary Spasm Who Have an Initial Favorable Response.** James A. Hill, Robert L. Feldman, C. Richard Conti, Carol K. Hill, and Carl J. Pepine

30 **Prognostic Value of Resting and Submaximal Exercise Radionuclide Ventriculography After Acute Myocardial Infarction in High-Risk Patients With Single and Multivessel Disease.** Pascal Nicod, James R. Corbett, Brian G. Firth, Samuel E. Lewis, Robert E. Rude, Robert Huxley, and James T. Willerson

37 **Evaluation of a QRS Scoring System in Acute Myocardial Infarction: Relation to Infarct Size, Early Stage Left Ventricular Ejection Fraction, and Exercise Performance.** Yoshihiko Seino, Howard M. Staniloff, William E. Shell, David Mickle, Prediman K. Shah, and John K. Vyden

43 **Multiform Accelerated Idioventricular Rhythm in Acute Myocardial Infarction: Electrocardiographic Characteristics and Response to Verapamil.** Samuel Sclarovsky, Boris Strasberg, Jacob Fuchs, Ruben F. Lewin, Alexander Arditi, Eliezer Klainman, Oscar H. Kracoff, and Jacob Agmon

48 **Subcostal 2-Dimensional Echocardiographic Imaging of Peripheral Left Coronary Artery Aneurysms in Kawasaki Disease.** Toshiki Maeda, Hitoshi Yoshida, Takashi Funabashi, Shigekazu Nakaya, Shoji Takabatake, Takashi Ohno, and Noboru Taniguchi

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

55 **Prolongation of the Q-T Interval in Man During Sleep.** Kevin F. Browne, Eric Prystowsky, James J. Heger, Donald A. Chilson, and Douglas P. Zipes

60 **Relation of Mode of Induction and Cycle Length of Ventricular Tachycardia: Analysis of 104 Patients.** John U. Doherty, Michael G. Kienzle, Harvey L. Waxman, Alfred E. Buxton, Francis E. Marchlinski, and Mark E. Josephson

65 **Cardiac Arrest in Young, Ostensibly Healthy Patients: Clinical, Hemodynamic, and Electrophysiologic Findings.** D. Woodrow Benson, Jr., David G. Benditt, Robert W. Anderson, Ann Dunnigan, Marc R. Pritzker, Thomas J. Kulik, and James H. Zavoral

70 **Value of the Ajmaline-Procainamide Test to Predict the Effect of Long-Term Oral Amiodarone on the Anterograde Effective Refractory Period of the Accessory Pathway in the Wolff-Parkinson-White Syndrome.** Pedro Brugada, Willem R. Dassen, Simon Braat, Anton P. Gorgels, and Hein J. J. Wellens

73 **Evaluation of Metoprolol in Suppressing Complex Ventricular Arrhythmias.** Craig M. Pratt, Sheila C. Yepsen, M. G. Kim Bloom, Addison A. Taylor, James B. Young, and Miguel A. Quinones

79 **Syncope and Ventricular Tachycardia in Patients With Ventricular Preexcitation.** Elwyn A. Lloyd, Richard N. Hauer, Douglas P. Zipes, James J. Heger, and Eric N. Prystowsky

83 **Efficacy, Safety, and Pharmacokinetics of a Concentration-Maintaining Regimen of Intravenous Pirmenol.** Michael J. Reiter, Stephen C. Hammill, David G. Shand, Chako Verghese, Elizabeth McCarthy, and Edward L. C. Pritchett

88 **Current Physiologic Pacemakers: A Serious Problem With a New Device.** Joseph W. Rubin, Martin J. Frank, John P. Boineau, and Robert G. Ellison

92 **Left Ventricular Function at Rest and During Exercise in Congenital Complete Heart Block: A Radionuclide Angiographic Evalution.** Bruno V. Manno, A-Hamid Hakki, Eshagh Eshaghpour, and Abdulmassih S. Iskandrian

95 **Idiopathic Paroxysmal Ventricular Tachycardia With a QRS Pattern of Right Bundle Branch Block and Left Axis Deviation: A Unique Clinical Entity With Specific Properties.** Fun-Chung Lin, C. David Finley, Shahbudin H. Rahimtoola, and Delon Wu

CONGESTIVE HEART FAILURE

101 **Platelet Alpha$_2$ Adrenoreceptors in Chronic Congestive Heart Failure.** Robert J. Weiss, Michael Tobes, Curtis E. Wertz, and Charles B. Smith

CONGENITAL HEART DISEASE

106 **Cardiovascular Effects of Breathing 95 Percent Oxygen in Children With Congenital Heart Disease.** Robert H. Beekman, Albert P. Rocchini, and Amnon Rosenthal

112 **Altered Baroreceptor Function in Children With Systolic Hypertension After Coarctation Repair.** Robert H. Beekman, Barry P. Katz, Catherine Moorehead-Steffens, and Albert P. Rocchini

118 **Two-Dimensional Echocardiographic Assessment of Caval and Pulmonary Venous Pathways After the Senning Operation.** Alvin J. Chin, Stephen P. Sanders, Roberta G. Williams, Peter Lang, William I. Norwood, and Aldo R. Castaneda

127 **Computer Interpretation of Pediatric Frank Vectorcardiograms in the Evaluation of Congenital Heart Disease.** Christian R. Brohet, Christiane Derwael-Barchy, Annie Robert, Robert Fesler, Mady Styns, Lucien A. Brasseur, and André Vliers

Continued on page A10

133 **Glucose and Insulin Changes in Infants and Children Undergoing Hypothermic Open-Heart Surgery.** George Benzing III, Paul D. Francis, Samuel Kaplan, James A. Helmsworth, and Mark A. Sperling

CARDIOMYOPATHY

137 **Cardiac Amyloidosis Causing Cardiac Dysfunction: Analysis of 54 Necropsy Patients.** William C. Roberts and Bruce F. Waller

147 **Cardiac Thrombosis and Thromboembolism in Chronic Chagas' Heart Disease.** J. Samuel M. Oliveira, Rosaly R. Correa De Araujo, Marcos A. Navarro, and Gerson Muccillo

MISCELLANEOUS TOPICS

152 **Aortic Valve Closure and Cardiac Vibrations in the Genesis of the Second Heart Sound.** Markku Kupari

155 **Analysis of the Amount of Tricuspid Valve Anular Dilatation Required to Produce Functional Tricuspid Regurgitation.** Jose L. Ubago, Alvaro Figueroa, Alberto Ochoteco, Thierry Colman, Rafael M. Duran, and Carlos G. Duran

159 **Effect of Pericardiocentesis on Right and Left Ventricular Function and Volumes in Pericardial Effusion.** Dante E. Manyari, William J. Kostuk, and Paul Purves

163 **Acute Effects of Phlebotomy on Right Ventricular Size and Performance in Polycythemic Patients With Chronic Obstructive Pulmonary Disease.** Allan D. Erickson, William A. Golden, Ben C. Claunch, Walter E. Donat, and John T. Kaemmerlen

167 **Left Ventricular Performance During Exercise: Response of Ear Densitogram Derivative.** Bruce G. Haffty, Tetsuro Sugiura, Nancy E. O'Hare, and David H. Spodick

172 **Effect of Cimetidine on the Pharmacokinetics and Pharmacodynamics of Quinidine.** Brian G. Hardy, Istvan T. Zador, Lawrence Golden, David Lalka, and Jerome J. Schentag

EXPERIMENTAL STUDIES

177 **Relation Between Functional Response to Nitroglycerin and Extent of Myocardial Necrosis in Dogs: Mapping of the Left Ventricle by 2-Dimensional Echocardiography.** Keicho Shimoura, Samuel Meerbaum, Tatsuo Sakamaki, Shuji Kondo, Michael C. Fishbein, Jacob Y-Rit, Chuwa Tei, Pravin M. Shah, and Eliot Corday

184 **Nuclear Magnetic Resonance Imaging of Acute Myocardial Infarction in Dogs: Alterations in Magnetic Relaxation Times.** Charles B. Higgins, Robert Herfkens, Martin J. Lipton, Richard Sievers, Philip Sheldon, Leon Kaufman, and Lawrence E. Crooks

189 **Effects of Coronary Occlusion on Flow in the Distribution of a Neighboring Stenotic Coronary Artery in the Dog.** Jeffrey S. Schwartz, Jay N. Cohn, and Robert J. Bache

196 **Roles of the Right Ventricular Free Wall and Ventricular Septum in Right Ventricular Performance and Influence of the Parietal Pericardium During Right Ventricular Failure in Dogs.** Masato Tani

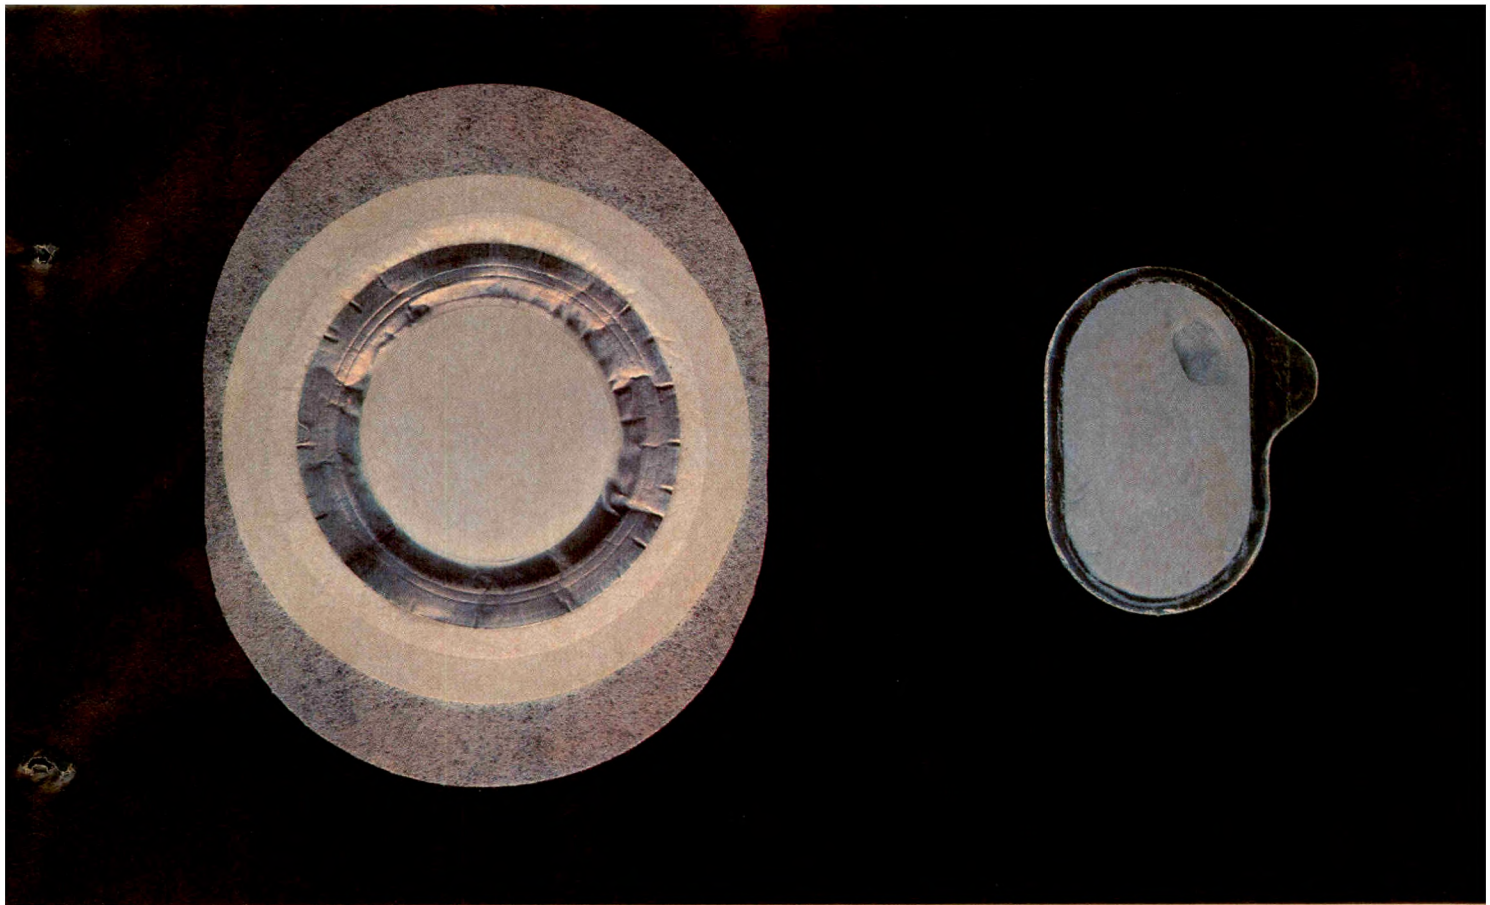
CORRECTION

In the May 1, 1983 issue on page 1377 (*Savage DD et al: Prevalence of Submitral [Anular] Calcium and its Correlates in a General Population-Based Sample [The Framingham Study]*), Table III contained 2 errors:

1. The data on atrial fibrillation are from offspring *and* original cohort subjects, whereas the remainder of the data in the Table are derived only from original cohort subjects.

2. Of the cohort subjects without submitral calcium, 6% (not 26%) had ≥ grade 3 murmurs.



The one on the left has three times more adhesive surface.

Nitro-Dur™ (nitroglycerin) Transdermal Infusion System 10cm², on the left, has three times the adhesive surface area of the comparable Ciba product (5 mg). Nitro-Dur 20 cm² provides twice the adhesive surface area as the comparable Ciba product (10 mg). The wide adhesive strip assures good matrix-to-skin contact and helps keep the system sealed and in place. It also separates easily from the backing, for easy opening and application. By contrast, the Ciba product has minimal outside adhesion. The adhesive lies primarily on the central surface through which the drug must pass.

A wide adhesive strip. It's just one reason why Nitro-Dur is the most widely prescribed transdermal nitroglycerin system.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

The most widely prescribed transdermal nitroglycerin system.

Please see next page for a summary of prescribing information.

Nitro-Dur™
(nitroglycerin)
Transdermal Infusion System

DESCRIPTION: The Nitro-Dur Transdermal Infusion System contains nitroglycerin in a gel-like matrix composed of glycerin, water (purified), lactose, polyvinyl alcohol, povidone and sodium citrate to provide a continuous source of the active ingredient. Nitro-Dur is available in dosage sizes 5cm², 10cm², 15cm² and 20cm², containing 26 mg, 51 mg, 77 mg and 104 mg of nitroglycerin, respectively, thereby providing precise dosing levels of nitroglycerin. Nitro-Dur has a rated release in vivo of approximately 0.5mg/cm²/24 hours. Each unit is sealed in a polyester-foil-polyethylene laminate. The bandage portion consists of a medical grade non-woven, heat sealable, microporous tape.

CLINICAL PHARMACOLOGY: When the Nitro-Dur system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before deactivation by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation with resultant reduction in cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In bioavailability studies,[1] transdermal absorption of nitroglycerin from the gel-like matrix achieved steady state venous plasma levels comparable to that of sublingual nitroglycerin and maintained these levels for 24 hours. Therapeutic effect is achieved within 30 minutes after application of the unit, and persists about 30 minutes after removal of the unit.

INDICATIONS AND USAGE: Prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS: The Nitro-Dur system should be used under careful clinical and/or hemodynamic monitoring in patients with acute myocardial infarction or congestive heart failure.

In terminating treatment of angina patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks in order to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension, may be due to overdosage. If during the course of treatment these symptoms occur, the dosage should be reduced.

Nitro-Dur is not intended for use in the treatment of acute anginal attacks. For this purpose, occasional use of sublingual nitroglycerin may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are administered. Headaches should be treated with mild analgesics while continuing Nitro-Dur therapy. If headache persists, the Nitro-Dur dosage should be reduced.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. Except for dermatitis, these symptoms are attributed to the pharmacologic effects of nitroglycerin. However, they may be symptoms of overdosage. When they persist, the Nitro-Dur dosage should be reduced or use of the product discontinued.

HOW SUPPLIED: Nitro-Dur Transdermal Infusion System, 5cm², 10cm², 15cm² and 20cm², is available in unit dose packages of 28 and hospital packs of 100.

CAUTION: Federal law prohibits dispensing without a prescription.

PATIENT INSTRUCTIONS FOR APPLICATION: Patient instructions are furnished with each unit dose package.

For complete prescribing information, please see package insert.

BIG NEWS IN HOLTER DATA ANALYSIS

DEL MAR AVIONICS

This tiny chip is a big reason why the Trendsetter® II System analyzes ambulatory ECG data so precisely.

Advanced electronics, capable of processing more than 5 million instructions per second, make the Trendsetter II design concept the most thorough approach ever developed to scanning Holter tapes.

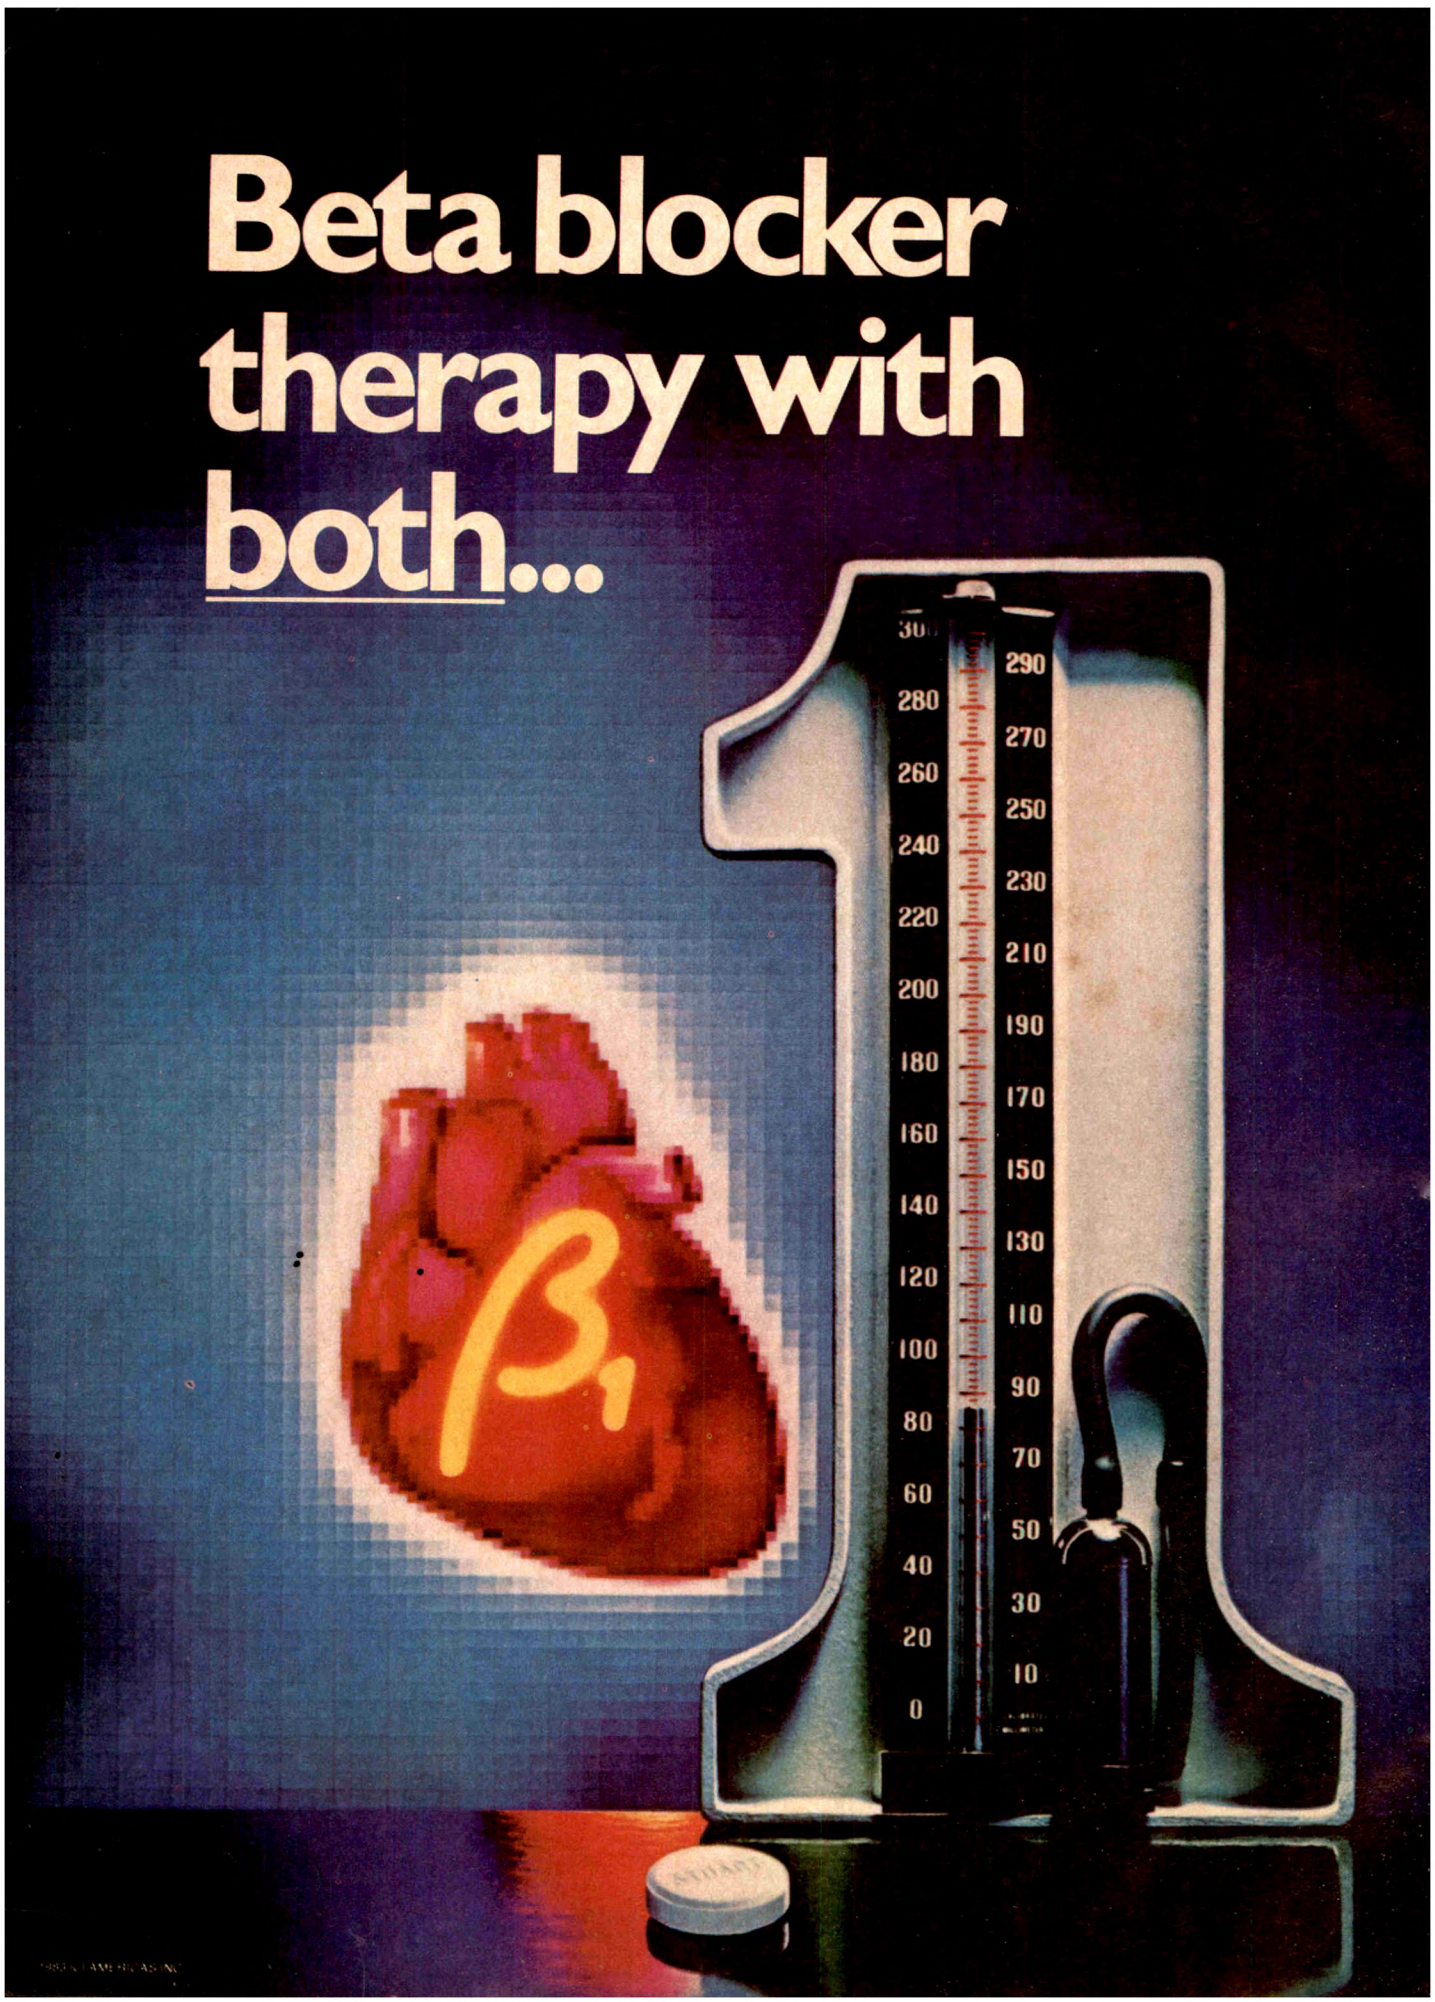
Accurate arrhythmia analysis is accomplished by morphology comparison, using variable, patient specific analysis parameters. These include bradycardia rate and interval; pause interval; T-wave amplitude; V-tach minimum rate; SVE minimum rate and prematurity; and selectable R-on-T adjustments for intrinsic heart rate variations. You get accurate and verifiable results on all patients — from pediatric to adult.

Additionally, arrhythmia analysis is enhanced by dedicated circuitry for manipulating artifactual data. Artifact can either be recognized and classified, or be deleted from analysis. So there's no artifact distortion.

The Trendsetter II System also features Express Trac,™ an advanced method of instantly analyzing and quantifying significant arrhythmia — with no operator intervention.

For more details on the Holter system designed with your precise patient needs in mind, contact Del Mar Avionics, 1601 Alton Avenue, Irvine, CA 92714 (714) 549-1500, Telex 68-31110 or 68-5621.

Beta blocker therapy with both...



one-tablet-a-day dosage and...

cardioselectivity*

ONE TABLET A DAY

TENORMIN®

(atenolol)

Tablets 50 mg

*Cardioselectivity denotes a relative preference for β_1 receptors, located chiefly in cardiac tissue. This preference is not absolute.

See last page of this advertisement for brief summary of prescribing information.

STUART PHARMACEUTIC

TENORMIN® (atenolol)

A beta$_1$-selective blocking agent for hypertension.

INDICATIONS AND USAGE: TENORMIN (atenolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide-type diuretic.

CONTRAINDICATIONS: TENORMIN is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see WARNINGS).

WARNINGS: Cardiac Failure: Sympathetic stimulation is necessary in supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, TENORMIN should be administered cautiously. Both digitalis and atenolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, TENORMIN therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents in patients with coronary artery disease, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Therefore, such patients should be cautioned against interruption of therapy without the physician's advice. Even in the absence of overt angina pectoris, when discontinuation of TENORMIN is planned, the patient should be carefully observed and should be advised to limit physical activity to a minimum. TENORMIN should be reinstated if withdrawal symptoms occur.

Bronchospastic Diseases: PATIENTS WITH BRONCHOSPASTIC DISEASE SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta, selectivity, however, TENORMIN may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta, selectivity is not absolute the lowest possible dose of TENORMIN should be used, with therapy initiated at 50 mg and a beta$_2$-stimulating agent (bronchodilator) made available. If dosage must be increased, dividing the dose should be considered in order to achieve lower peak blood levels.

Anesthesia and Major Surgery: As with all beta-receptor blocking drugs it may be decided to withdraw TENORMIN before surgery. In this case, 48 hours should be allowed to elapse between the last dose and anesthesia. If treatment is continued, care should be taken when using anesthetic agents which depress the myocardium, such as ether, cyclopropane, and trichloroethylene.

TENORMIN, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects on the heart can be reversed by administration of such agents (eg, dobutamine or isoproterenol with caution—see OVERDOSAGE). Manifestations of excessive vagal tone (eg, profound bradycardia, hypotension) may be corrected with atropine (1-2 mg I.V.).

Diabetes and Hypoglycemia: TENORMIN should be used with caution in diabetic patients if a beta-blocking agent is required. Beta blockers may mask tachycardia occurring with hypoglycemia, but other manifestations such as dizziness and sweating may not be significantly affected. TENORMIN does not potentiate insulin-induced hypoglycemia and, unlike nonselective beta blockers, does not delay recovery of blood glucose to normal levels.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (eg, tachycardia) of hyperthyroidism. Abrupt withdrawal of beta blockade might precipitate a thyroid storm; therefore, patients suspected of developing thyrotoxicosis from whom TENORMIN therapy is to be withdrawn should be monitored closely.

PRECAUTIONS: Impaired Renal Function: The drug should be used with caution in patients with impaired renal function (see DOSAGE AND ADMINISTRATION).

Drug Interactions: Catecholamine-depleting drugs (eg, reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with TENORMIN plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Should it be decided to discontinue therapy in patients receiving beta blockers and clonidine concurrently, the beta blocker should be discontinued several days before the gradual withdrawal of clonidine.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Two long-term (maximum dosing duration of 18 or 24 months) rat studies and one long-term (maximum dosing duration of 18 months) mouse study, each employing dose levels as high as 300 mg/kg/day or 150 times the maximum recommended human dose, did not indicate a carcinogenic potential in rodents. Results of various mutagenicity studies support this finding.

Fertility of male or female rats (evaluated at dose levels as high as 200 mg/kg/day or 100 times the maximum recommended human dose) was unaffected by atenolol administration.

Animal Toxicology: Chronic studies performed in animals have revealed the occurrence of vacuolation of epithelial cells of Brunner's glands in the duodenum of both male and female dogs at all tested dose levels of atenolol (starting at 15 mg/kg/day or 7.5 times the maximum recommended human dose) and increased incidence of atrial degeneration of hearts of male rats at 300 mg but not 150 mg atenolol/kg/day (150 and 75 times the maximum recommended human dose, respectively).

USAGE IN PREGNANCY: Pregnancy Category C. Atenolol has been shown to produce a dose-related increase in embryo/fetal resorptions in rats at doses equal to or greater than 50 mg/kg or 25 or more times the maximum recommended human dose. Although similar effects were not seen in rabbits, the compound was not evaluated in rabbits at doses above 25 mg/kg or 12.5 times the maximum recommended human dose. There are no adequate and well-controlled studies in pregnant women. TENORMIN should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: It is not established to what extent this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving atenolol.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS: Most adverse effects have been mild and transient. Frequency estimates were derived from controlled studies in which adverse reactions were either volunteered by the patient (U.S. studies) or elicited (eg, by checklist—foreign studies). The reported frequency of elicited adverse effects was higher for both TENORMIN and placebo-treated patients than when these reactions were volunteered. Where frequency of adverse effects for TENORMIN and placebo is similar, causal relationship is uncertain.

The following adverse-reaction data present frequency estimates in terms of percentages: first from the U.S. studies (volunteered side effects) and then from both U.S. and foreign studies (volunteered and elicited side effects):

U.S. STUDIES (% ATENOLOL-% PLACEBO):

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (0%-0.5%), postural hypotension (2%-1%), leg pain (0%-0.5%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (4%-1%), vertigo (2%-0.5%), light-headedness (1%-0%), tiredness (0.6%-0.5%), fatigue (3%-1%), lethargy (1%-0%), drowsiness (0.6%-0%), depression (0.6%-0.5%), dreaming (0%-0%)

GASTROINTESTINAL: diarrhea (2%-0%), nausea (4%-1%)

RESPIRATORY (See WARNINGS): wheeziness (0%-0%), dyspnea (0.6%-1%)

TOTALS U.S. AND FOREIGN STUDIES:

CARDIOVASCULAR: bradycardia (3%-0%), cold extremities (12%-5%), postural hypotension (4%-5%), leg pain (3%-1%)

CENTRAL NERVOUS SYSTEM/NEUROMUSCULAR: dizziness (13%-6%), vertigo (2%-0.2%), light-headedness (3%-0.7%), tiredness (26%-13%), fatigue (6%-5%), lethargy (3%-0.7%), drowsiness (2%-0.5%), depression (12%-9%), dreaming (3%-1%)

GASTROINTESTINAL: diarrhea (3%-2%), nausea (3%-1%)

RESPIRATORY (see WARNINGS): wheeziness (3%-3%), dyspnea (6%-4%)

MISCELLANEOUS: There have been reports of skin rashes and/or dry eyes associated with the use of beta-adrenergic blocking drugs. The reported incidence is small and, in most cases, the symptoms have cleared when treatment was withdrawn. Discontinuance of the drug should be considered if any such reaction is not otherwise explicable. Patients should be closely monitored following cessation of therapy.

POTENTIAL ADVERSE EFFECTS: In addition, a variety of adverse effects have been reported with other beta-adrenergic blocking agents, and may be considered potential adverse effects of TENORMIN (atenolol).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Fever, combined with aching and sore throat, laryngospasm and respiratory distress.

Central Nervous System: Reversible mental depression progressing to catatonia, visual disturbances, hallucinations, an acute reversible syndrome characterized by disorientation of time and place, short-term memory loss, emotional lability with slightly clouded sensorium, decreased performance on neuropsychometrics.

Gastrointestinal: Mesenteric arterial thrombosis, ischemic colitis.

Other: Reversible alopecia, Peyronie's disease, erythematous rash, Raynaud's phenomenon.

Miscellaneous: The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with TENORMIN during investigational use and foreign marketing experience. Furthermore, a number of patients who had previously demonstrated established practolol reactions were transferred to TENORMIN therapy with subsequent resolution or quiescence of the reaction.

OVERDOSAGE: To date, there is no known case of acute overdosage, and no specific information on emergency treatment of overdosage is available. The most common effects expected with overdosage of a beta-adrenergic blocking agent are bradycardia, congestive heart failure, hypotension, bronchospasm, and hypoglycemia.

In the case of overdosage, treatment with TENORMIN should be stopped and the patient carefully observed. TENORMIN can be removed from the general circulation by hemodialysis. In addition to gastric lavage, the following therapeutic measures are suggested if warranted:

Bradycardia: Atropine or another anticholinergic drug.

Heart Block (Second or Third Degree): Isoproterenol or transvenous cardiac pacemaker.

Congestive Heart Failure: Conventional therapy.

Hypotension (Depending on Associated Factors): Epinephrine rather than isoproterenol or norepinephrine may be useful in addition to atropine and digitalis.

Bronchospasm: Aminophylline, isoproterenol, or atropine.

Hypoglycemia: Intravenous glucose.

DOSAGE AND ADMINISTRATION: The initial dose of TENORMIN is 50 mg given as one tablet a day either alone or added to diuretic therapy. The full effect of this dose will usually be seen within one to two weeks. If an optimal response is not achieved, the dosage should be increased to TENORMIN 100 mg given as one tablet a day. Increasing the dosage beyond 100 mg a day is unlikely to produce any further benefit.

TENORMIN may be used alone or concomitantly with other antihypertensive agents including thiazide-type diuretics, hydralazine, prazosin, and alpha-methyldopa.

Since TENORMIN is excreted via the kidneys, dosage should be adjusted in cases of severe impairment of renal function. No significant accumulation of TENORMIN occurs until creatinine clearance falls below 35 ml/min/1.73 m^2 (normal range is 100-150 ml/min/1.73 m^2); therefore, the following maximum dosages are recommended for patients with renal impairment:

Creatinine Clearance (ml/min/1.73 m^2)	Atenolol Elimination Half-life (hrs)	Maximum Dosage
15-35	16-27	50 mg daily
<15	>27	50 mg every other day

Patients on hemodialysis should be given 50 mg after each dialysis; this should be done under hospital supervision as marked falls in blood pressure can occur.

HOW SUPPLIED: Tablets of 50 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 105 embossed on the other side are supplied in monthly calendar packages of 28 tablets, bottles of 100 tablets, and unit-dose packages of 100 tablets. Tablets of 100 mg TENORMIN (atenolol): round, flat, uncoated, white tablets with Stuart embossed on one side and NDC No. 101 embossed on the other side are supplied in bottles of 100 tablets and unit-dose packages of 100 tablets.

Protect from heat, light, and moisture. Store unit-dose and calendar packages at controlled room temperature.

CORONARY HEART DISEASE

1 **Intracoronary Thrombus in Nontransmural Myocardial Infarction and in Unstable Angina Pectoris**

JAY B. MANDELKORN, NELSON M. WOLF, SURENDER SINGH, JAY A. SHECHTER, ROBERT I. KERSH, DAVID M. RODGERS, MARK B. WORKMAN, LAMBERTO G. BENTIVOGLIO, STEVEN M. LaPORTE, and STEVEN G. MEISTER, *With the technical assistance of* BARBARA TUCKER

To determine whether intracoronary thrombus occurs in nontransmural myocardial infarction (MI) or unstable angina pectoris (UA), coronary arteriography was performed before and after intracoronary nitroglycerin and streptokinase infusion in 17 patients. None of the 8 nontransmural MI patients and 1 of 9 patients with UA responded to intracoronary nitroglycerin. Seven nontransmural MI patients and 4 patients with UA responded to streptokinase infusion with opening of an occluded vessel, an increase in stenotic diameter, or dissolution of an intracoronary filling defect. Serial opening and closing of ischemia-related vessels occurred spontaneously and in response to streptokinase in some patients in whom thrombolysis was demonstrated. Evidence of thrombolysis was not seen in any patient studied longer than 1 week from the onset of the rest pain syndrome. The findings of thrombolysis in several patients with nontransmural MI and UA suggest that intracoronary thrombus formation plays a pathogenetic role in some patients with these ischemic syndromes.

7 **Comparison of High-Dose and Medium-Dose Propranolol in the Relief of Exercise-Induced Myocardial Ischemia**

KENNETH G. MORRIS, MICHAEL B. HIGGINBOTHAM, R. EDWARD COLEMAN, DAVID G. SHAND, and FREDERICK R. COBB

This study compared the effects of medium-dose (160 mg/day) and high-dose (480 mg/day) propranolol on symptoms and objective indexes of left ventricular ischemia in 22 males with coronary artery disease and typical angina pectoris. Patients were assessed at rest and during exercise to the pretreatment maximum work load. Medium-dose propranolol improved the functional class in 11 of 22 patients, reduced heart rate and blood pressure, and reduced the incidence of exercise-induced chest pain and electrocardiographic S-T segment depression. The radionuclide ejection fraction and wall motion score were unchanged at rest but were significantly improved during exercise. High-dose propranolol improved the functional class in 4 other patients and further reduced exercise-induced chest pain and S-T segment depression; the ejection fraction and wall motion score further improved in several other patients, although the change was not significant for the group. This study provides objective evidence that high doses of propranolol provide additional relief of ischemia and may improve symptoms in patients who do not respond to commonly used doses.

14 **Anatomic and Prognostic Significance of New T-Wave Inversion in Unstable Angina**

DAVID E. HAINES, DANIEL S. RAABE, WALTER D. GUNDEL, and FRANS J. Th. WACKERS

Patients with unstable angina may demonstrate gradual development of T-wave inversion without biochemical evidence of myocardial necrosis. In 118 consecutive patients with unstable angina, new T-wave inversion ($\geq$2 mm) occurred in 47 patients (40%). This finding was correlated with coronary angiographic findings and follow-up. In patients who underwent coronary angiography, new T-wave inversion in anterior leads correlated with significant stenosis of the left anterior descending coronary artery (sensitivity 69%, specificity 89%, and positive predictive value 86%). In patients who had follow-up on medical treatment, new T-wave inversion correlated with a significantly higher incidence of myocardial infarction and cardiac death. New T-wave inversion on the electrocardiogram of patients with unstable angina identifies a subgroup with significant coronary artery disease and a poor prognosis on medical treatment.

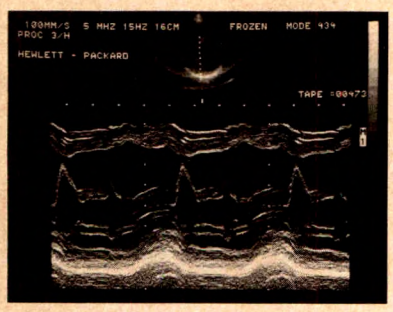
Will the echocardiography decision you make today still be a sound investment tomorrow.

It will be if you choose Hewlett-Packard's Cardiac Imaging System. Why?



Today, our real time phased array System produces artifact-free images that are crisp and clear, with well-defined boundaries. Dynamic focusing assures sharpness at all depths. And an extended gray scale clearly reveals variations in cardiac tissue.

Tomorrow, our modular System can be upgraded as new Hewlett-Packard technological developments lead to enhancements in cardiac imaging. Our latest advancement? 5MHz phased array imaging. It provides ultra-high resolution for both pediatric and adult patients.

Now you can choose from five different transducers so you can scan a wide variety of patients. Quickly and easily.

Display simultaneous 2-D sector and single or dual M-mode. View it in real time on the screen. Tape it. Freeze it. Or generate a strip chart recording.

What's more, our microprocessor-based system is highly reliable. When service is needed, it's both fast and economical.

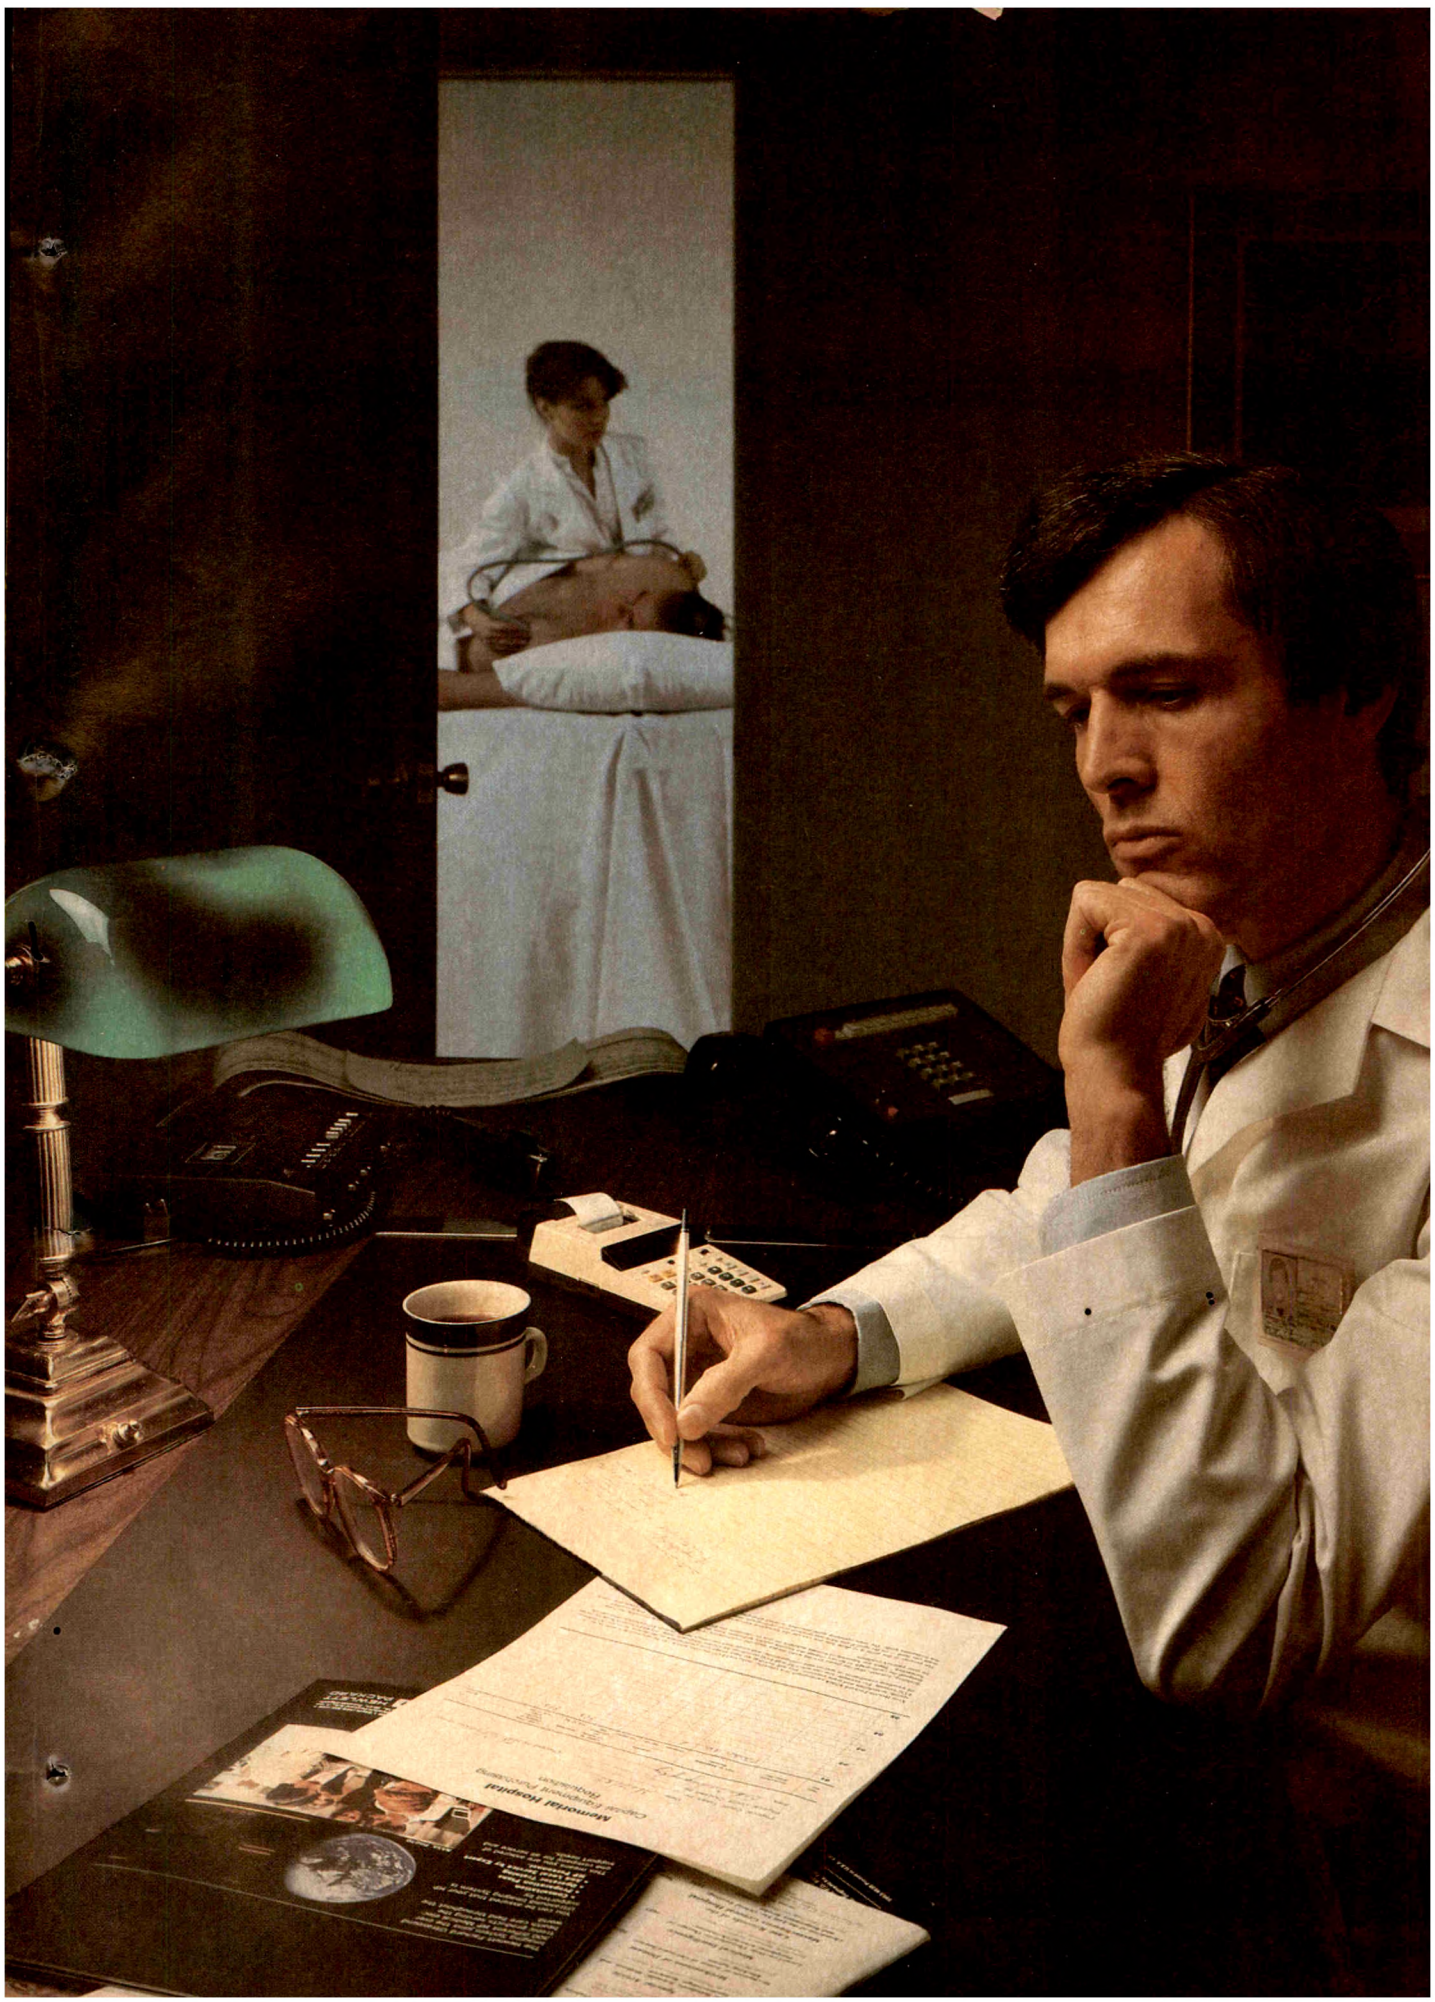
Plus, Hewlett-Packard's system is easy to use. It even includes a comprehensive analysis package for automatic computation of cardiac parameters and report generation.

And the compact system is mobile, so it can be moved from Echo Lab to CCU to Surgery.

Image quality, upgradability, versatility, reliability and Hewlett-Packard's worldwide commitment to service and support. It all adds up to a sound investment. Today and tomorrow. For more information, call your local HP Sales Office listed in the telephone directory white pages and ask for the Medical Systems Department, or write to us: Hewlett-Packard, 100 Fifth Avenue, Waltham, Massachusetts 02254. Do it today. **The Ultra Sound Investment.**

HEWLETT PACKARD

MGO3307



Memorial Hospital
Cancer Treatment Procedure
Radiation

Indications: Premature atrial and ventricular contractions, aproxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, paroxysmal ventricular tachycardia when not associated with complete heartblock, maintenance therapy after electrical conversion of atrial fibrillation and/or flutter.

Contraindications: Intraventricular conduction defects. A-V block. Idiosyncrasy or hypersensitivity.

Aberrant impulses and abnormal rhythms due to escape mechanisms should not be treated with quinidine.

Warning: In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio and resulting in extremely rapid ventricular rate.

Precautions: All the precautions applying to regular quinidine therapy apply to the Extentab form. Use with care in patients with severe congestive failure, renal insufficiency or with digitalis intoxication.

Patients should be carefully observed for signs of toxicity: e.g., (1) allergy or idiosyncrasy, such as febrile reactions, skin eruptions, and thrombocytopenia (extremely rare); (2) "cinchonism," such as tinnitus, blurred vision, dizziness, light-headedness, and tremor; (3) G.I. symptoms (nausea, vomiting, diarrhea, and colic); (4) cardiotoxic effects such as ventricular extrasystoles occurring at the rate of one or more every 6 normal beats, an increase of the QRS complex of 50% or more, a complete A-V block, or ventricular tachycardia.

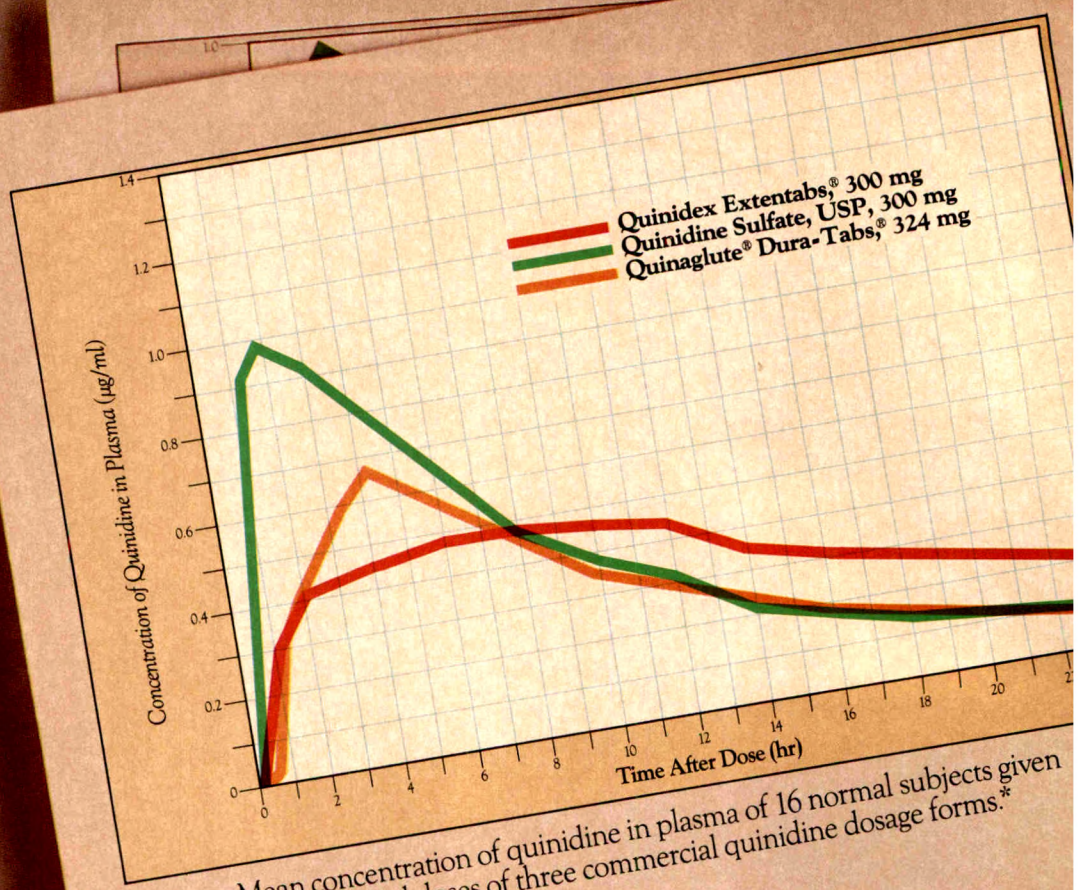
NOTE: The development of "cinchonism" is not usually sufficient reason for terminating quinidine therapy. G.I. symptoms can also be minimized by giving the drug with food.

Adverse Reactions: Cases of quinidine-induced hypoprothrombinemic hemorrhage in patients on chronic anticoagulant drug therapy have been reported.

Dosage: Two Quinidex Extentabs every 8 to 12 hours.

How Supplied: White sugar-coated Extentabs in bottles of 100 (NDC 0031-6649-63) and 250 (NDC 0031-6649-67) and Dis-co® Unit Dose Packs of 100 (NDC 0031-6649-64).

Rev. Dec. 1981



Mean concentration of quinidine in plasma of 16 normal subjects given single oral doses of three commercial quinidine dosage forms.*

Consider The Evidence For Quinidex (Quinidine Sulfate, USP), 300 mg Extentabs®

- The convenience of b.i.d. dosage*
- Up to 12 hours of smooth, sustained release
- Relative bioavailability equal to Quinidine Sulfate Tablets, USP
- Contains 48 mg more active quinidine than the leading gluconate product

*Some patients may require a t.i.d. dosage schedule.

19 **Ventricular Tachyarrhythmias in Prinzmetal's Variant Angina: Clinical Significance and Relation to the Degree and Time Course of S-T Segment Elevation**

MARIO PREVITALI, CATHERINE KLERSY, JORGE A. SALERNO, MARCELLO CHIMIENTI, CLAUDIO PANCIROLI, EGIDIO MARANGONI, GIUSEPPE SPECCHIA, MARIO COMOLLI, and PIERO BOBBA

Ventricular tachyarrhythmias were documented during ischemic attacks in 27 of 56 patients (48%) with variant angina studied with continuous electrocardiographic monitoring. In 23 of 27 patients, ventricular arrhythmias developed during maximal S-T segment elevation (occlusion arrhythmias) and in 10 during return of S-T segment to baseline (reperfusion arrhythmias). Patients with ventricular tachyarrhythmias did not differ from those without arrhythmias in regard to clinical, electrocardiographic, and angiographic findings. Both occlusion and reperfusion arrhythmias were correlated with the degree of S-T segment elevation; reperfusion arrhythmias were also related to the duration of acute ischemia. These data suggest that in variant angina, ventricular tachyarrhythmias may be triggered either by vasospastic coronary occlusion or by reperfusion after relief of spasm. Severity and duration of ischemia appear to be the main determinants of the arrhythmias, while clinical and angiographic characteristics are not good predictors of their presence.

26 **Long-Term Responses to Nifedipine in Patients With Coronary Spasm Who Have an Initial Favorable Response**

JAMES A. HILL, ROBERT L. FELDMAN, C. RICHARD CONTI, CAROL K. HILL, and CARL J. PEPINE

Fourteen patients with coronary spasm selected because of a good short-term (4 weeks) decrease in angina frequency with nifedipine were followed up for an average of 9.4 months. Of these patients, 12 (86%) had a continued good response (transient slight increase or no change), but 8 (67%) required therapy in addition to nifedipine (nitrates, beta blockers, surgery) to maintain angina control. In 5 patients (36%), nifedipine therapy was limited because of adverse effects. Three patients had unstable angina requiring hospitalization during this time. Patients with coronary spasm selected because of a favorable short-term reduction in angina frequency with nifedipine were effectively treated over the long term with nifedipine, but additional therapy was often needed to control symptoms. Adverse effects were common, but dose reduction usually diminished these effects.

30 **Prognostic Value of Resting and Submaximal Exercise Radionuclide Ventriculography After Acute Myocardial Infarction in High-Risk Patients With Single and Multivessel Disease**

PASCAL NICOD, JAMES R. CORBETT, BRIAN G. FIRTH, SAMUEL E. LEWIS, ROBERT E. RUDE, ROBERT HUXLEY, and JAMES T. WILLERSON

In patients who survive the acute phase of myocardial infarction, those with multivessel coronary artery disease generally have a worse prognosis than those with single-vessel disease. However, some with significant multivessel stenoses have a good prognosis, whereas some with a significant single-vessel stenosis have a poor prognosis. Other factors, including the degree of left ventricular dysfunction at rest, have an important bearing on prognosis. The present study suggests that functional alterations in radionuclide-determined left ventricular volumes and ejection fraction during submaximal exercise testing may be of more prognostic importance than the delineation of coronary arterial anatomy or the assessment of residual ventricular function at rest in this setting.

37 **Evaluation of a QRS Scoring System in Acute Myocardial Infarction: Relation to Infarct Size, Early Stage Left Ventricular Ejection Fraction, and Exercise Performance**

YOSHIHIKO SEINO, HOWARD M. STANILOFF, WILLIAM E. SHELL, DAVID MICKLE, PREDIMAN K. SHAH, and JOHN K. VYDEN

The quantitative values of the recently proposed QRS scoring system (QRSs) using a standard 12-lead electrocardiogram in the early stage of acute myocardial infarction (AMI) were evaluated in terms of (1) how the QRSs actually correlated with enzymatically estimated infarct size and left ventricular ejection fraction (LVEF) determined by multiple-gated equilibrium cardiac blood pool scintigraphy, and (2) the relation to exercise test results soon after AMI. QRSs significantly correlated with infarct size ($r = 0.72$) and LVEF ($r = -0.71$). Also, the QRSs significantly related to exercise tolerance, exercise symptoms, and exercise S-T changes. These data suggest that the QRSs in the early stage of AMI will be clinically useful not only as a variable that correlates with infarct size and LVEF, but also as an aid in early identification of exercise performance soon after AMI.

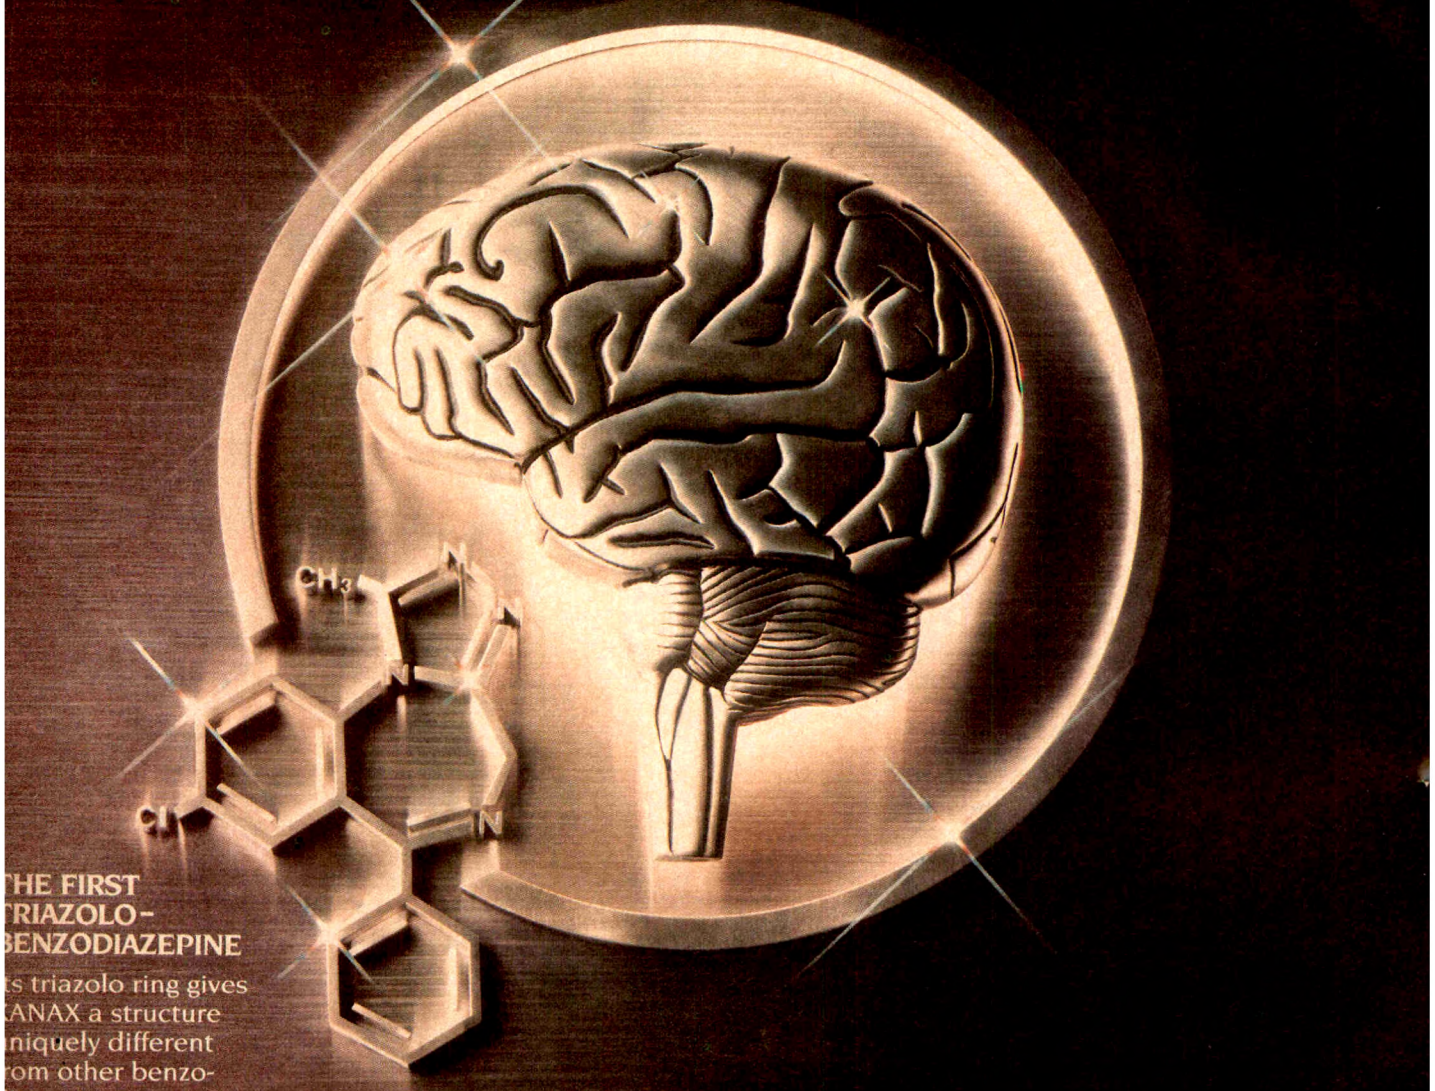
Xanax® 0.5 mg Tablets

alprazolam C-IV



THE FIRST TRIAZOLO-BENZODIAZEPINE

ts triazolo ring gives ANAX a structure niquely different om other benzo-iazepines.

THE FIRST OF A UNIQUE CLASS

Upjohn

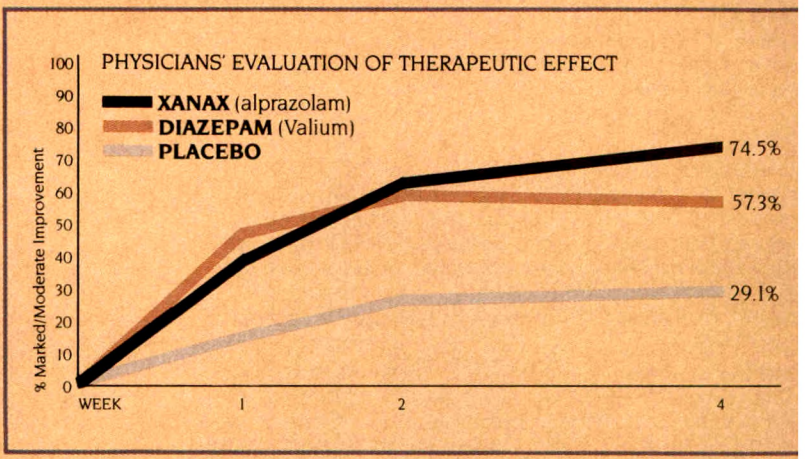
© 1982 The Upjohn Company

FOR CLINICAL ANXIETY

EFFICACY EQUAL TO DIAZEPAM WITH LESS DROWSINESS

In double-blind, placebo-controlled clinical trials in 976 patients with moderate to severe clinical anxiety, therapy with XANAX was compared to diazepam (Valium).*

Patients treated with XANAX *had a significantly lower incidence of drowsiness when compared directly to diazepam* therapy (Valium) in *a 976-patient,* placebo-controlled, multicenter study.*

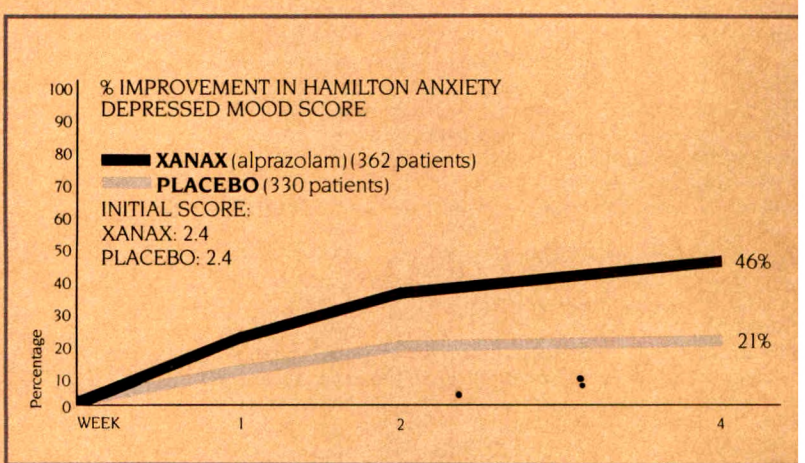


AND CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOM

EFFECTIVE IN CLINICAL ANXIETY WITH DEPRESSIVE SYMPTOMS

Patients with clinical anxiety may complain of having feelings of depression, such as sadness, blueness, or loneliness.

Depressed mood is one of 14 items on the Hamilton Anxiety Rating Scale. Special analysis of 692 anxious patients with a significant depressed mood item score showed that treatment with XANAX was significantly better than placebo in decreasing depressed mood score.



SIMPLE DOSAGE:
XANAX 0.25–0.5 mg T.I.D.

The usual starting dose of XANAX is 0.25 to 0.5 mg, three times daily.

Please see next page for brief summary of prescribing information.

P 24, 134

Xanax® 0.5 mg Tablets
alprazolam Ⓒ

XANAX® Tablets ℞
(alprazolam)

CONTRAINDICATIONS
Patients with sensitivity to this drug or other benzodiazepines and in acute narrow angle glaucoma.

WARNINGS
Not of value in psychotic patients. Caution patients against hazardous occupations requiring complete mental alertness and about the simultaneous ingestion of alcohol and other CNS depressant drugs.

Benzodiazepines can cause fetal harm in pregnant women. Warn patients of the potential hazard to the fetus. Avoid during the first trimester.

PRECAUTIONS
General: If XANAX is combined with other psychotropics or anticonvulsant drugs, consider drug potentiation (see Drug Interaction section). Exercise the usual precautions regarding size of the prescription for depressed or suicidal patients. In elderly and debilitated patients, use the lowest possible dosage (see Dosage and Administration). Observe the usual precautions in treating patients with impaired renal or hepatic function.

Information for Patients: Alert patients about (a) consumption of alcohol and drugs, (b) possible fetal abnormalities, (c) operating machinery or driving, (d) not increasing dose of the drug due to risk of dependence, (e) not stopping the drug abruptly. *Laboratory Tests:* Not ordinarily required in otherwise healthy patients. *Drug Interactions:* Additive CNS depressant effects with other psychotropics, anticonvulsants, antihistamines, ethanol and other CNS depressants. Pharmacokinetic interactions with benzodiazepines have been reported. *Drug/Laboratory Test Interactions:* No consistent pattern for a specific drug or specific test. *Carcinogenesis, Mutagenesis, Impairment of Fertility:* No carcinogenic potential or impairment of fertility in rats. *Pregnancy:* See Warnings. *Nonteratogenic Effects:* The child born of a mother on benzodiazepines may be at some risk for withdrawal symptoms and neonatal flaccidity. *Labor and Delivery:* No established use. *Nursing Mothers:* Benzodiazepines are excreted in human milk. Women on XANAX should not nurse. *Pediatric Use:* Safety and effectiveness in children below the age of 18 have not been established.

ADVERSE REACTIONS
Side effects are generally observed at the beginning of therapy and usually disappear with continued medication. In the usual patient, the most frequent side effects are likely to be an extension of the pharmacological activity of XANAX, e.g., drowsiness or lightheadedness.

Central Nervous System: Drowsiness, lightheadedness, depression, headache, confusion, insomnia, nervousness, syncope, dizziness, akathisia, and tiredness/sleepiness.

Gastrointestinal: Dry mouth, constipation, diarrhea, nausea/vomiting and increased salivation.

Cardiovascular: Tachycardia/palpitations, and hypotension.

Sensory: Blurred vision.

Musculoskeletal: Rigidity and tremor.

Cutaneous: Dermatitis/allergy.

Other Side Effects: Nasal congestion, weight gain, and weight loss.

In addition, the following adverse events have been reported with the use of anxiolytic benzodiazepines: dystonia, irritability, concentration difficulties, anorexia, loss of coordination, fatigue, sedation, slurred speech, jaundice, musculoskeletal weakness, pruritus, diplopia, dysarthria, changes in libido, menstrual irregularities, incontinence and urinary retention.

Paradoxical reactions such as stimulation, agitation, increased muscle spasticity, sleep disturbances, and hallucinations may occur. Should these occur, discontinue the drug.

During prolonged treatment, periodic blood counts, urinalysis, and blood chemistry analyses are advisable. Minor EEG changes, of unknown significance, have been observed.

DRUG ABUSE AND DEPENDENCE
Physical and Psychological Dependence: Withdrawal symptoms have occurred following abrupt discontinuance of benzodiazepines. After prolonged therapy, dosage should be tapered. *Controlled Substance Class:* XANAX is a controlled substance and has been assigned to schedule IV.

CAUTION: FEDERAL LAW PROHIBITS DISPENSING WITHOUT PRESCRIPTION.

BS-1

*Cohn JB: Multicenter double-blind efficacy and safety study comparing alprazolam, diazepam and placebo in clinically anxious patients. *J Clin Psychiatry* 42 (9):347-351, 1981.

43 Multiform Accelerated Idioventricular Rhythm in Acute Myocardial Infarction: Electrocardiographic Characteristics and Response to Verapamil

SAMUEL SCLAROVSKY, BORIS STRASBERG, JACOB FUCHS, RUBEN F. LEWIN, ALEXANDER ARDITI, ELIEZER KLAINMAN, OSCAR H. KRACOFF, and JACOB AGMON

This study describes 13 patients with acute myocardial infarction in whom multiform accelerated idioventricular rhythm (AIVR) developed. In all patients the arrhythmia was intermittent and benign, caused no hemodynamic compromise, and was not associated with serious ventricular arrhythmias. Multiform AIVR with 2 morphologies was detected in 7 cases, with 3 morphologies in 5 cases, and with 4 morphologies in 1 case. Intravenous verapamil was given in 6 patients. It caused no change in the rate of AIVR in 1 patient, decreased the rate of AIVR by 20 beats/min in 1 patient and abolished the arrhythmia in 4 patients.

48 Subcostal 2-Dimensional Echocardiographic Imaging of Peripheral Left Coronary Artery Aneurysms in Kawasaki Disease

TOSHIKI MAEDA, HITOSHI YOSHIDA, TAKASHI FUNABASHI, SHIGEKAZU NAKAYA, SHOJI TAKABATAKE, TAKASHI OHNO, and NOBORU TANIGUCHI

Coronary aneurysm is an ominous complication of Kawasaki disease associated with a risk of sudden death. Two-dimensional (2-D) echocardiography can be used to visualize coronary aneurysms with use of the parasternal horizontal approach at the level of the aorta. However, this approach visualizes only limited areas of the proximal segments of the coronary arteries. A previous study provided a 2-D echocardiographic technique to detect peripheral right coronary aneurysms using the subcostal approach. An additional study was performed to detect peripheral coronary aneurysms of the left coronary artery from the ostium to terminal sites in both left anterior descending and left circumflex arteries, using the subcostal approach. In this study, 3 aneurysms at the origin of the obtuse marginal artery (1 in segment 13 and 2 at the origin of the second diagonal branch) were visualized with 2-D echocardiography. These echocardiographic studies were done prospectively and their features coincided well in size, shape, and anatomic location with confirmatory angiographic appearances.

ARRHYTHMIAS AND CONDUCTION DISTURBANCES

55 Prolongation of the Q-T Interval in Man During Sleep

KEVIN F. BROWNE, ERIC PRYSTOWSKY, JAMES J. HEGER, DONALD A. CHILSON, and DOUGLAS P. ZIPES

Parasympathetic blockade shortens the duration of the Q-T interval and ventricular effective refractory period independent of heart rate change. Since relative parasympathetic effect increases during sleep, it was determined whether sleep was associated with a change in the Q-T interval. Fifteen patients receiving no drugs underwent 3 to 6 days of continuous electrocardiographic recording. Comparison of R-R intervals that had similar durations during sleep and awake states revealed that the duration of the Q-T interval was longer during sleep in all 15 patients. Comparison of linear regression lines in 8 patients who had a sufficient range of overlap of R-R intervals demonstrated that the regression lines during sleep were significantly different from those during the awake state. The difference in the Q-T interval between awake and sleeping states was 19 ± 7 ms when calculated at a heart rate of 60 beats/min. These statistical comparisons of the Q-T and R-R intervals indicate that the Q-T interval is longer during sleep than awake state at the same heart rate. Prolongation of the Q-T interval during sleep may reflect increased parasympathetic tone or sympathetic withdrawal. These changes in repolarization may be related to the diurnal variation of some ventricular arrhythmias.

60 Relation of Mode of Induction and Cycle Length of Ventricular Tachycardia: Analysis of 104 Patients

JOHN U. DOHERTY, MICHAEL G. KIENZLE, HARVEY L. WAXMAN, ALFRED E. BUXTON, FRANCIS E. MARCHLINSKI, and MARK E. JOSEPHSON

In 104 patients with ventricular tachycardia (VT), the cycle length (CL) was correlated with the mode of initiation (single, double, and triple extrastimuli and rapid pacing). VT induced with a single extrastimulus was slower (342 ± 72 ms, mean CL) than that induced with double (295 ± 60 ms) or triple (282 ± 56 ms) extrastimuli or rapid pacing (293 ± 40 ms). There was no difference among the last 3 groups. Thirty-eight patients had endocardial catheter mapping, and the distance between site of stimulation and origin of VT was determined. There was no difference in mode of initiation when the stimulation site was close, intermediate, or distant from the site of origin. Mode of initiation was also correlated with site of previous myocardial infarction in 69 patients initiated from the right ventricular apex. Mode of initiation did not differ among patients with septal, inferior, lateral, or multiple myocardial infarctions. Thus, the CL of VT initiated with a single extrastimulus was slower than that initiated with double or triple extrastimuli or rapid pacing, and the mode of initiation was unrelated to the site of previous myocardial infarction or to the distance between stimulation site and site of origin of VT.

NITRODISC™
(NITROGLYCERIN)
5 mg/24 hr
10 mg/24 hr discs

DESCRIPTION: Nitrodisc incorporates a patented Microseal Drug Delivery™ system consisting of a solid, nitroglycerin-impregnated polymer bonded to a flexible, non-sensitizing adhesive bandage. It is designed to be applied topically. Nitrodisc provides constant and controlled drug delivery over a uniform skin surface area for 24 hours.

Nitrodisc is available in two strengths which release either 5 mg or 10 mg of nitroglycerin during a 24-hour period. The 5 mg/24 hr system contains 16 mg nitroglycerin over an 8 cm^2 releasing surface. The 10 mg/24 hr system contains 32 mg nitroglycerin over a 16 cm^2 releasing surface.

INDICATIONS AND USAGE: Nitrodisc is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS: Nitrodisc (nitroglycerin) is contraindicated in patients known to be intolerant of organic nitrate drugs, and in patients with marked anemia, increased intraocular pressure, or increased intracranial pressure.

WARNINGS: In patients with acute myocardial infarction or congestive heart failure, Nitrodisc should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of patients with angina, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent potential withdrawal reactions, which are characteristic of all vasodilators in the nitrate class.

PRECAUTIONS: Symptoms of hypotension, such as faintness, weakness, or dizziness, particularly orthostatic hypotension, may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Nitrodisc is not intended for immediate relief of anginal attacks. For this purpose, occasional use of sublingual preparations may be necessary.

ADVERSE REACTIONS: Transient headache is the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Nitrodisc therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist, Nitrodisc (nitroglycerin) dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION: Nitrodisc should be applied once each day. To use Nitrodisc, follow the instructions on the package. Nitrodisc should be applied to an intact skin site free of hair and not subject to excessive movement. It should not be applied to the distal parts of the extremities. A suitable area should be shaved free of hair, if necessary. The application site should be changed slightly each time to avoid undue skin irritation. A new Nitrodisc should be applied if the product loosens.

The optimal dosage regimen should be selected based upon the clinical response, the side effects, and the effects of therapy upon blood pressure and heart rate. It is recommended that therapy be initiated with the smaller Nitrodisc, and that the larger Nitrodisc be utilized when a greater response is desired. In the event that higher doses are necessary, multiple pads may be applied.

65 Cardiac Arrest in Young, Ostensibly Healthy Patients: Clinical, Hemodynamic, and Electrophysiologic Findings

D. WOODROW BENSON, Jr., DAVID G. BENDITT, ROBERT W. ANDERSON, ANN DUNNIGAN, MARC R. PRITZKER, THOMAS J. KULIK, and JAMES H. ZAVORAL

This study examines the clinical, hemodynamic, and electrophysiologic findings in a unique group of 11 young (aged 15 months to 29 years) survivors of cardiac arrest. All patients were previously in good health, and cardiac arrest was the initial manifestation of cardiac disease. Overt clinical and hemodynamic abnormalities were not as common as previously reported, and in some instances apparent cardiac abnormalities failed to provide a link to cardiac arrest. However, during multicatheter electrophysiologic study, sustained tachyarrhythmia was reproducibly initiated in 8 of 11 patients (73%). Treatment to prevent recurrence of cardiac arrest was difficult in this group of patients.

70 Value of the Ajmaline-Procainamide Test to Predict the Effect of Long-Term Oral Amiodarone on the Anterograde Effective Refractory Period of the Accessory Pathway in the Wolff-Parkinson-White Syndrome

PEDRO BRUGADA, WILLEM R. DASSEN, SIMON BRAAT, ANTON P. GORGELS, and HEIN J. J. WELLENS

A retrospective study was undertaken in 36 patients with the Wolff-Parkinson-White (WPW) syndrome to assess the value of an ajmaline/procainamide test to predict the effect of chronic oral amiodarone on the duration of the anterograde effective refractory period (ANT ERP) of the accessory pathway. Before amiodarone, in 24 patients (group A) ajmaline (24 patients) (50 mg intravenously over 3 minutes) or procainamide (11 patients) (10 mg/kg body weight intravenously over 10 minutes) failed to block anterograde conduction over the accessory pathway during sinus rhythm (a negative ajmaline/procainamide test). In 12 patients (group B), ajmaline (12 patients) or procainamide (7 patients) blocked anterograde conduction over the accessory pathway during sinus rhythm (a positive test). The two groups differed in the duration of the ANT-ERP of the accessory pathway measured at control study (237 ± 24 ms in group A and 284 ± 25 ms in group B, $p < 0.05$). After oral amiodarone (total dose 8,400 to 11,200 mg over 4 to 6 weeks), 83% of the patients in group A had an ANT-ERP of the accessory pathway of 260 to 330 ms and 83% of the patients in group B had an ANT-ERP of the accessory pathway of ≥330 ms ($p < 0.01$). Thus, ajmaline/procainamide testing performed before initiation of amiodarone therapy is of value in predicting the results of oral amiodarone on the duration of the ANT-ERP of the accessory pathway in the WPW syndrome.

73 Evaluation of Metoprolol in Suppressing Complex Ventricular Arrhythmias

CRAIG M. PRATT, SHEILA C. YEPSEN, M. G. KIM BLOOM, ADDISON A. TAYLOR, JAMES B. YOUNG, and MIGUEL A. QUINONES

Twenty patients with cardiac disease and complex ventricular ectopy were studied using a placebo-controlled, single-blind protocol (3-day placebo; 3-day metoprolol, 100 mg/day; 4-day metoprolol, 200 mg/day) and continuous ambulatory electrocardiographic monitoring. Although high-dose metoprolol suppressed only 60% of all premature ventricular beats, it was increasingly effective in suppressing pairs and ventricular tachycardia (84 and 94% suppression, respectively). The mean plasma peak metoprolol levels to achieve this reduction was 72 ± 34 ng/ml. At this plasma metoprolol level, beta blockade was demonstrated by a decrease in mean 24-hour heart rate during normal activity from 78 ± 8 to 62 ± 4 beats/min ($p < 0.001$). While the resting left ventricular ejection fraction was unaffected by this plasma metoprolol level, pulmonary function including forced expiratory volume and forced vital capacity was significantly reduced, but returned to normal with metaproterenol.

79 Syncope and Ventricular Tachycardia in Patients With Ventricular Preexcitation

ELWYN A. LLOYD, RICHARD N. HAUER, DOUGLAS P. ZIPES, JAMES J. HEGER, and ERIC N. PRYSTOWSKY

Patients with the Wolff-Parkinson-White syndrome may have syncope caused by arrhythmias involving the accessory pathway: for example, atrioventricular reentrant tachycardia at a rapid rate or atrial fibrillation with a fast ventricular response due to conduction over the accessory pathway. However, these patients are not exempt from other causes of syncope. Four patients with ventricular preexcitation are presented whose syncope was initially attributed to an arrhythmia utilizing the accessory pathway. At electrophysiologic study, the electrophysiologic properties of the accessory pathways were considered unlikely to support tachycardia of a rate sufficient to result in syncope, but ventricular tachycardia was induced in all patients and was thought to be the cause of syncope in 3.

for many post-MI patients...

Cardio-protective.

Cardioprotective is a word you won't find in standard medical dictionaries.

But you will find it appearing in the medical literature. And you will be hearing it in medical discussions. Until dictionaries recognize the term, MSD invites you to use this as a working definition of *cardioprotective:*

"reduction of the risk of reinfarction and cardiac mortality for many stabilized post-MI patients."

We at MSD feel it is appropriate to bring you this definition of cardioprotective since it was MSD that brought you the impressive clinical data[1] that documented the cardioprotective benefits of BLOCADREN® (Timolol Maleate, MSD) for many stabilized patients who have survived the acute phase of a myocardial infarction.

[1]The Norwegian Multicenter Study Group: Timolol-induced reduction in mortality and reinfarction in patients surviving acute myocardial infarction, N. Engl. J. Med. 304(14):801-807, April 2, 1981.

BLOCADREN is contraindicated in patients with bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see below); cardiogenic shock; and hypersensitivity to this product.

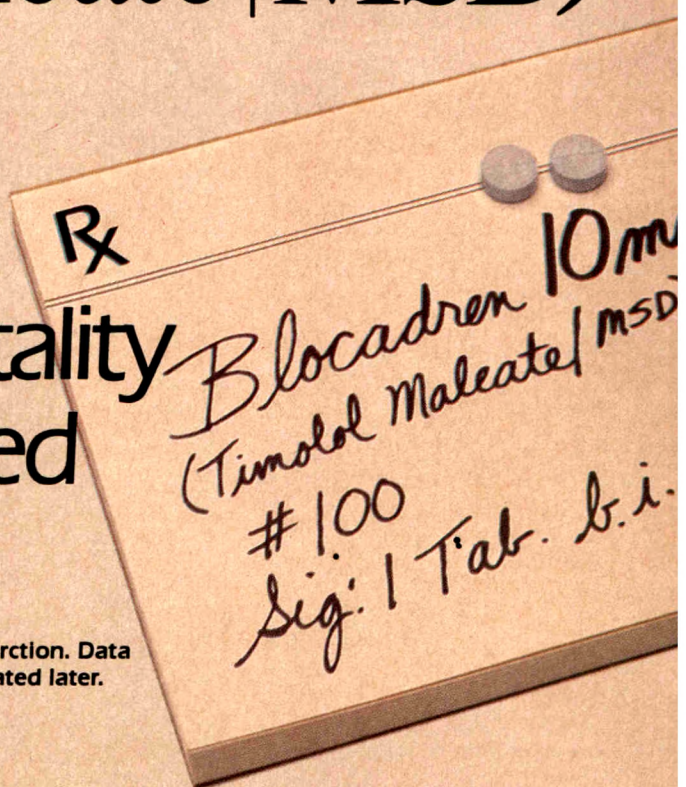
Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated.

In patients without a history of cardiac failure, continued depression of the myocardium with beta-blocking agents over a

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy, exacerbation of angina and, in some cases, myocardial infarction have occurred after **abrupt** discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart

Blocadren®
(Timolol Maleate | MSD)

reduces the risk of reinfarction and cardiac mortality for many stabilized post-MI patients



Treatment should be initiated within 1 to 4 weeks after infarction. Data are not available as to whether benefit would ensue if initiated later.

disease, the dosage should be gradually reduced over a period of one to two weeks, and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

MSD
MERCK SHARP & DOHME

BLOCADREN®
(TIMOLOL MALEATE | MSD)

CONTRAINDICATIONS:

Bronchospasm, including bronchial asthma, or severe chronic obstructive pulmonary disease; sinus bradycardia; second- and third-degree atrioventricular block; overt cardiac failure (see WARNINGS); cardiogenic shock; hypersensitivity to this product.

WARNINGS:

Cardiac Failure: Sympathetic stimulation may be essential for support of the circulation in individuals with diminished myocardial contractility, and its inhibition by beta-adrenergic receptor blockade may precipitate more severe failure. Although beta blockers should be avoided in overt congestive heart failure, they can be used, if necessary, with caution in patients with a history of failure who are well compensated, usually with digitalis and diuretics. Both digitalis and timolol maleate slow AV conduction. If cardiac failure persists, therapy with BLOCADREN should be withdrawn.

In Patients without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of cardiac failure, patients receiving BLOCADREN should be digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues despite adequate digitalization and diuretic therapy, BLOCADREN should be withdrawn.

Exacerbation of Ischemic Heart Disease following Abrupt Withdrawal—Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered timolol maleate, particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, timolol maleate administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue timolol maleate therapy abruptly even in patients treated only for hypertension.

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. Beta-adrenergic receptor blockade impairs the ability of the heart to respond to beta-adrenergically mediated reflex stimuli. This may augment the risk of general anesthesia in surgical procedures. Some patients receiving beta-adrenergic receptor blocking agents have been subject to protracted severe hypotension during anesthesia. Difficulty in restarting and maintaining the heartbeat has also been reported. For these reasons, in patients undergoing elective surgery, some authorities recommend gradual withdrawal of beta-adrenergic receptor blocking agents.

If necessary during surgery, the effects of beta-adrenergic blocking agents may be reversed by sufficient doses of such agonists as isoproterenol, dopamine, dobutamine, or levarterenol.

Diabetes Mellitus: BLOCADREN should be administered with caution in patients subject to spontaneous hypoglycemia or to diabetic patients (especially those with labile diabetes) who are receiving insulin or oral hypoglycemic agents. Beta-adrenergic receptor blocking agents may mask the signs and symptoms of acute hypoglycemia.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

PRECAUTIONS:

General: *Impaired Hepatic or Renal Function*: Since BLOCADREN is partially metabolized in the liver and excreted mainly by the kidneys, dosage reductions may be necessary when hepatic and/or renal insufficiency is present.

Dosing in the Presence of Marked Renal Failure: Marked hypotensive responses have been seen in patients with marked renal impairment undergoing dialysis after 20-mg doses. Dosing in such patients should therefore be especially cautious.

Drug Interactions: Close observation of the patient is recommended when BLOCADREN is administered to patients receiving catecholamine-depleting drugs such as reserpine, because of possible additive effects and the production of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In a two-year study of timolol maleate in rats, there was a statistically significant ($p \leq 0.05$) increase in the incidence of adrenal pheochromocytomas in male rats administered 300 times the maximum recommended human dose (1 mg/kg/day). Similar differences were not observed in rats administered doses equivalent to 25 or 100 times the maximum recommended human dose. In a lifetime study in mice, there were statistically significant ($p \leq 0.05$) increases in the incidence of benign and malignant pulmonary tumors and benign uterine polyps in female mice at 500 mg/kg/day, but not at 5 or 50 mg/kg/day. There was also a significant increase in mammary adenocarcinomas at the 500-mg/kg/day dose. This was associated with elevations in serum prolactin which occurred in female mice administered timolol at 500 mg/kg, but not at doses of 5 or 50 mg/kg/day. An increased incidence of mammary adenocarcinomas in rodents has been associated with administration of several other therapeutic agents which elevate serum prolactin, but no correlation between serum prolactin levels and mammary tumors has been established in man. Furthermore, in adult human female subjects who received oral dosages of up to 60 mg of timolol maleate, the maximum recommended human oral dosage, there were no clinically meaningful changes in serum prolactin.

There was a statistically significant increase ($p \leq 0.05$) in the overall incidence of neoplasms in female mice at the 500-mg/kg/day dosage level.

Timolol maleate was devoid of mutagenic potential when evaluated *in vivo* (mouse) in the micronucleus test and cytogenetic assay (doses up to 800 mg/kg) and *in vitro* in a neoplastic cell transformation assay (up to 100 μg/ml). In Ames tests the highest concentrations of timolol employed, 5000 or 10,000 μg/plate, were associated with statistically significant elevations ($p \leq 0.05$) of revertants observed with tester strain TA100 (in seven replicate assays) but not in the remaining three strains. In the assays with tester strain TA100, no consistent dose response relationship was observed nor did the ratio of test to control revertants reach 2. A ratio of 2 is usually considered the criterion for a positive Ames test.

Studies in rats showed no adverse effect on male or female fertility at doses up to 150 times the maximum recommended human dose.

Pregnancy—Category C: Should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Because of the potential for serious adverse reactions from timolol in nursing infants, a decision should be made whether to discontinue nursing or to discontinue the drug, taking into account the importance of the drug to the mother.

Pediatric Use: Safety and effectiveness in children have not been established.

ADVERSE REACTIONS:

BLOCADREN is usually well tolerated in properly selected patients. Most adverse effects have been mild and transient.

In a multicenter (12-week) clinical trial comparing timolol maleate and placebo, the following adverse reactions were reported spontaneously and considered to be causally related to timolol maleate:

	Timolol Maleate (n=176) %	Placebo (n=168) %
BODY AS A WHOLE		
fatigue/tiredness	3.4	0.6
headache	1.7	1.8
chest pain	0.6	0
asthenia	0.6	0
CARDIOVASCULAR		
bradycardia	9.1	0
arrhythmia	1.1	0.6
syncope	0.6	0
edema	0.6	1.2
DIGESTIVE		
dyspepsia	0.6	0.6
nausea	0.6	0
INTEGUMENTARY		
pruritus	1.1	0
NERVOUS SYSTEM		
dizziness	2.3	1.2
vertigo	0.6	0
paresthesia	0.6	0
PSYCHIATRIC		
decreased libido	0.6	0
RESPIRATORY		
dyspnea	1.7	0.6
bronchial spasm	0.6	0
rales	0.6	0
SPECIAL SENSES		
eye irritation	1.1	0.6
tinnitus	0.6	0

These data are representative of the incidence of adverse effects that may be observed in a properly selected hypertensive patient population, e.g., a group excluding patients with bronchospastic disease, congestive heart failure, or other contraindications to beta-blocker therapy. These adverse reactions can also occur in patients with coronary artery disease.

In a different population, the coronary artery disease population, studied in the Norwegian multicenter trial (see CLINICAL PHARMACOLOGY), the frequency of the principal adverse reactions and the frequency with which these resulted in discontinuation of therapy in the timolol and placebo groups were:

	Adverse Reaction†		Withdrawal‡	
	Timolol (n=945) %	Placebo (n=939) %	Timolol (n=945) %	Placebo (n=939) %
Asthenia or Fatigue	5	1	<1	<1
Heart Rate <40 beats/minute	5	<1	4	<1
Cardiac Failure—Nonfatal	8	7	3	2
Hypotension	3	2	3	1
Pulmonary Edema—Nonfatal	2	<1	<1	<1
Claudication	3	3	1	<1

Nausea or Digestive Disorders	8	6	1	<1
Dizziness	6	4	1	0
Bronchial Obstruction	2	<1	1	<1

†When an adverse reaction recurred in a patient, it is listed only once.
‡Only principal reason for withdrawal in each patient is listed.

These adverse reactions can also occur in patients treated for hypertension.

The following additional adverse effects have been reported in clinical experience with the drug: *Body as a Whole*: extremity pain, decreased exercise tolerance, weight loss; *Cardiovascular*: cardiac failure, cerebral vascular accident, worsening of angina pectoris, worsening of arterial insufficiency, Raynaud's phenomenon, palpitations, vasodilatation; *Digestive*: gastrointestinal pain, hepatomegaly, vomiting, diarrhea, dyspepsia; *Endocrine*: hyperglycemia, hypoglycemia; *Integumentary*: rash, skin irritation, increased pigmentation, sweating; *Musculoskeletal*: arthralgia; *Nervous System*: local weakness; *Psychiatric*: depression, nightmares, somnolence, insomnia, nervousness, diminished concentration; *Respiratory*: cough; *Special Senses*: visual disturbances, dry eyes; *Urogenital*: impotence, urination difficulties.

Potential Adverse Effects: In addition, a variety of adverse effects not observed in clinical trials with BLOCADREN, but reported with other beta-adrenergic blocking agents, should be considered potential adverse effects of BLOCADREN: *Nervous System*: reversible mental depression progressing to catatonia; hallucinations, an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics; *Cardiovascular*: intensification of AV block (see CONTRAINDICATIONS); *Gastrointestinal*: mesenteric arterial thrombosis, ischemic colitis; *Hematologic*: agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura; *Allergic*: erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress; *Miscellaneous*: reversible alopecia, Peyronie's disease. Multisystem syndrome reported with practolol.

Clinical Laboratory Test Findings: Slight increases in blood urea nitrogen, serum potassium, and serum uric acid, and slight decreases in hemoglobin and hematocrit occurred, but were not progressive or associated with clinical manifestations.

CONTENTS

83 Efficacy, Safety, and Pharmacokinetics of a Concentration-Maintaining Regimen of Intravenous Pirmenol

MICHAEL J. REITER, STEPHEN C. HAMMILL, DAVID G. SHAND, CHAKO VERGHESE, ELIZABETH McCARTHY, and EDWARD L. C. PRITCHETT

A 3-stage, concentration-maintaining intravenous infusion regimen of pirmenol was tested for efficacy and safety in 8 subjects with chronic, stable premature ventricular beats. The regimen maintained stable plasma pirmenol levels of 0.94 to 2.75 mg/ml during infusions lasting up to 48 hours. In randomized, double-blind, placebo-controlled studies in 5 patients, pirmenol suppressed average premature ventricular beat frequency 93 ± 6% compared with control values. Pirmenol infusions were unassociated with adverse effects or toxicity. Pirmenol is therefore considered a promising antiarrhythmic agent.

88 Current Physiologic Pacemakers: A Serious Problem With a New Device

JOSEPH W. RUBIN, MARTIN J. FRANK, JOHN P. BOINEAU, and ROBERT G. ELLISON

This report describes the early results of treatment of symptomatic bradyarrhythmias in 20 patients with an automatic (DDD) pacemaker (Medtronic model 7000, Versatrax I). Nine patients had optimal DDD-mode pacing during 78 paced months. In 3 patients, the DDD mode was changed to atrioventricular sequential (DVI) early because of risk imposed by sustained tachycardia upon underlying myocardial ischemia. The other 8 had sustained tachycardia due to pacemaker reentry, and 7 developed neurologic and cardiovascular symptoms. DDD pacing was abandoned in 5 when reentry could not be interrupted by digitalis administration or reprogramming. Three continue to be paced in the DDD mode despite intermittent reentrant tachycardias; digitalis diminishes episodes of reentry in only 1. Reentrant tachycardia caused by the occurrence of slow retrograde atrioventricular conduction combined with a short, fixed atrial refractory period renders this pacemaker unsatisfactory for DDD-mode pacing in many patients.

92 Left Ventricular Function at Rest and During Exercise in Congenital Complete Heart Block: A Radionuclide Angiographic Evaluation

BRUNO V. MANNO, A-HAMID HAKKI, ESHAGH ESHAGHPOUR, and ABDULMASSIH S. ISKANDRIAN

Left ventricular function and volume were evaluated at rest and during upright exercise in 5 patients with congenital complete heart block by means of radionuclide ventriculography. Resting cardiac output was maintained at a normal level by an increase in end-diastolic volume rather than a decrease in end-systolic volume. The left ventricular ejection fraction was normal at rest in all patients but an abnormal response to exercise was noted in 3 patients. Thus, patients with congenital complete heart block utilize the Starling mechanism to maintain normal resting cardiac output, but the left ventricular response to exercise is usually abnormal even in the absence of symptoms.

95 Idiopathic Paroxysmal Ventricular Tachycardia With a QRS Pattern of Right Bundle Branch Block and Left Axis Deviation: A Unique Clinical Entity With Specific Properties

FUN-CHUNG LIN, C. DAVID FINLEY, SHAHBUDIN H. RAHIMTOOLA, and DELON WU

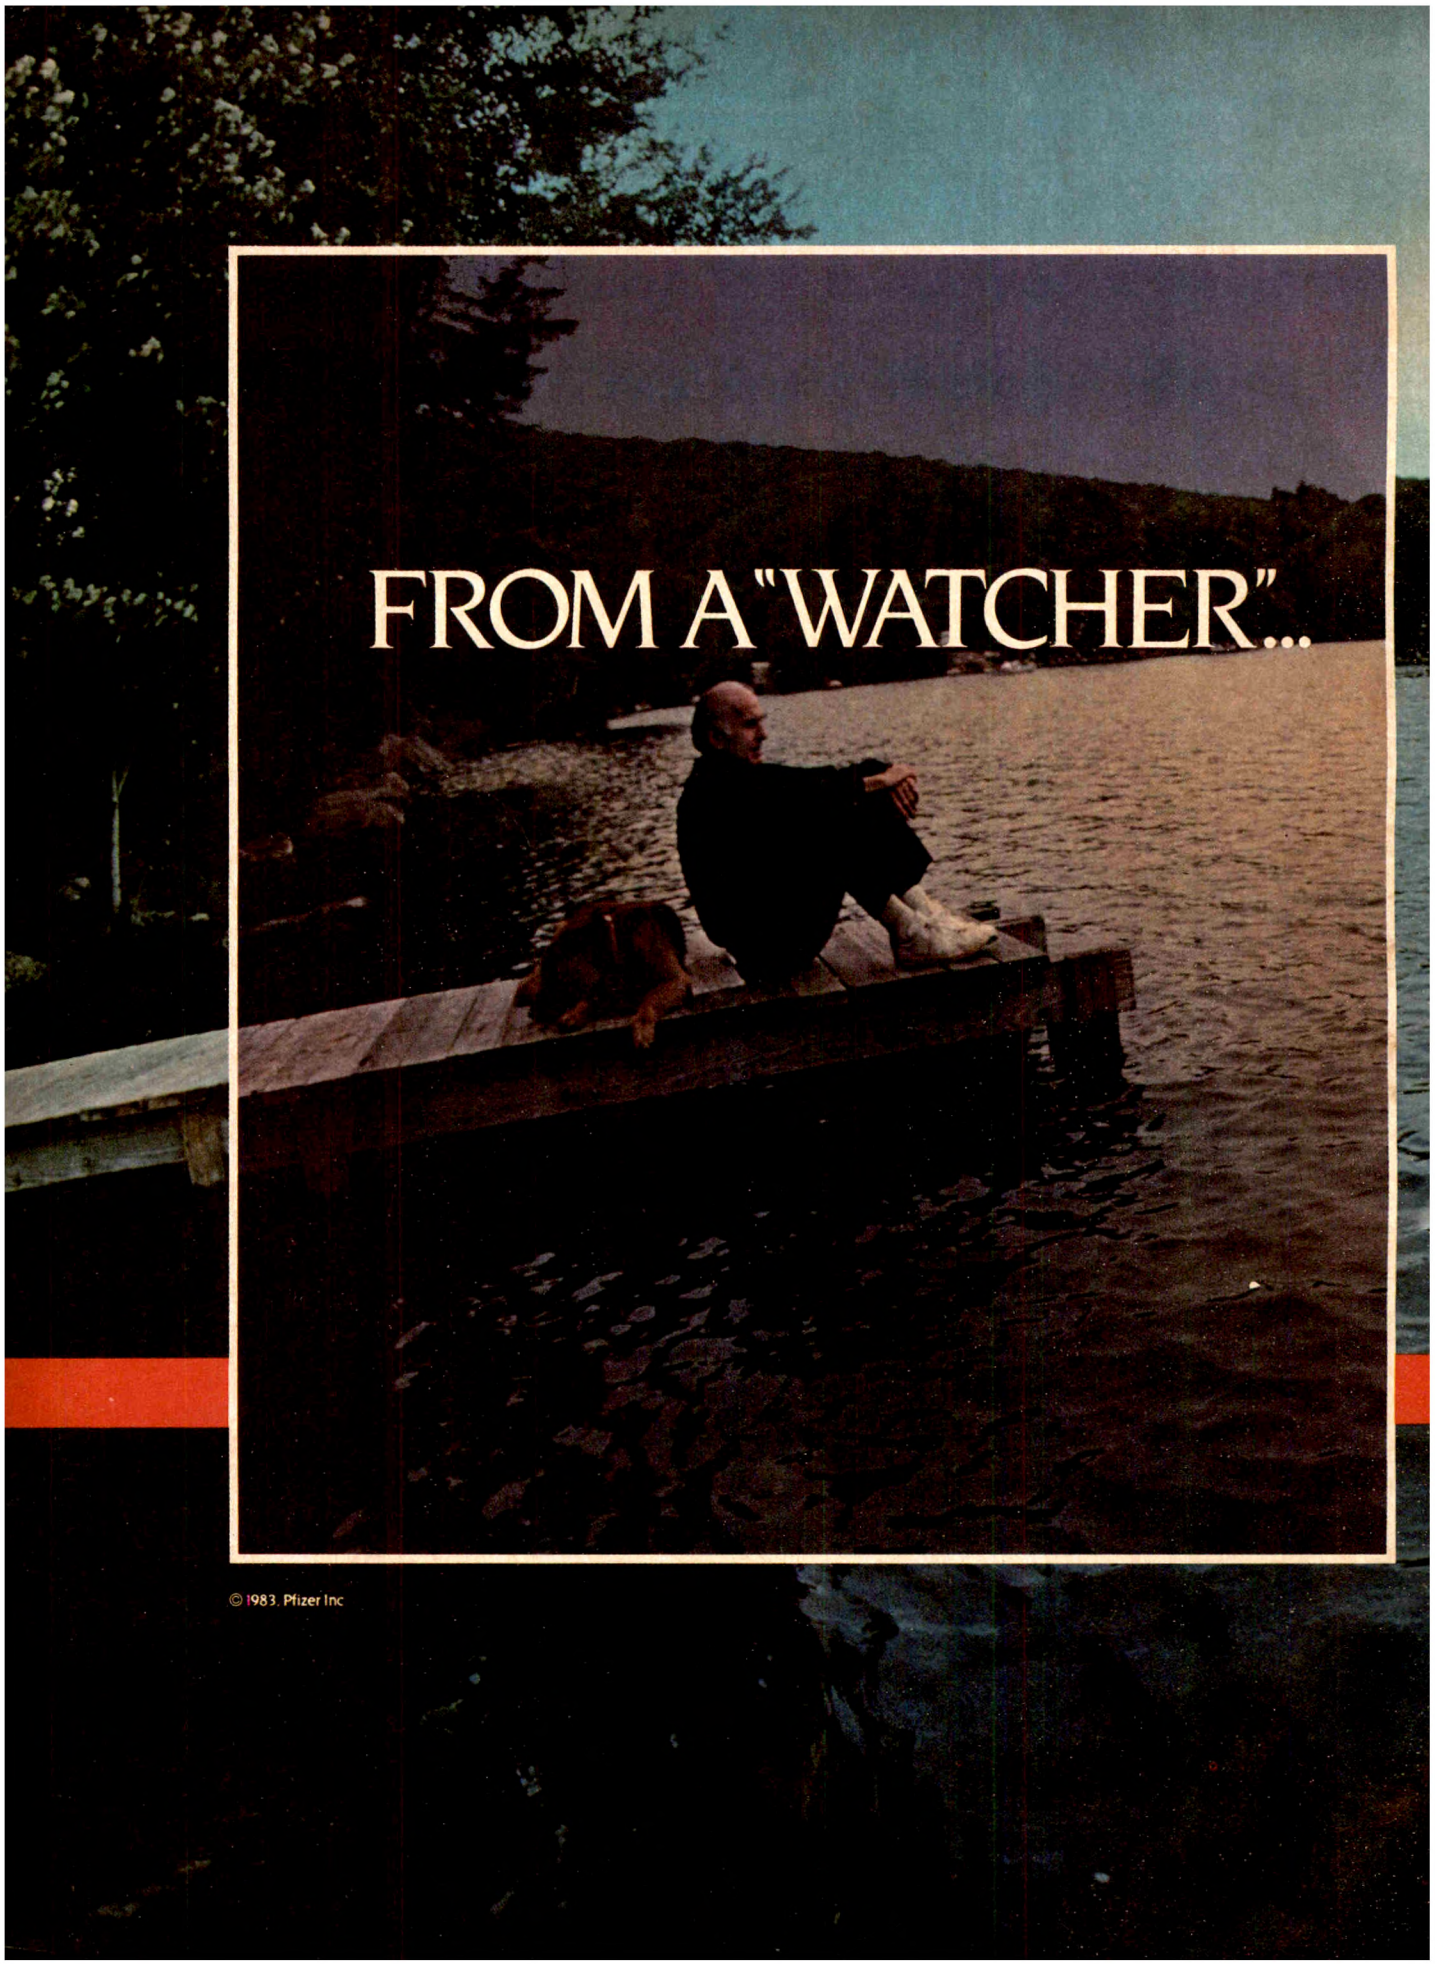
A distinct entity of recurrent, sustained ventricular tachycardia is reported in 4 young, asymptomatic patients without obvious heart disease. In these patients, the electrocardiogram during sinus rhythm showed a repolarization abnormality over inferior and lateral precordial leads. During tachycardia, the electrocardiogram showed a QRS pattern of right bundle branch block and left axis deviation. The tachycardia was inducible with electrical stimulation, highly responsive to verapamil, partially responsive to procainamide, and nonresponsive to lidocaine and propranolol.

CONGESTIVE HEART FAILURE

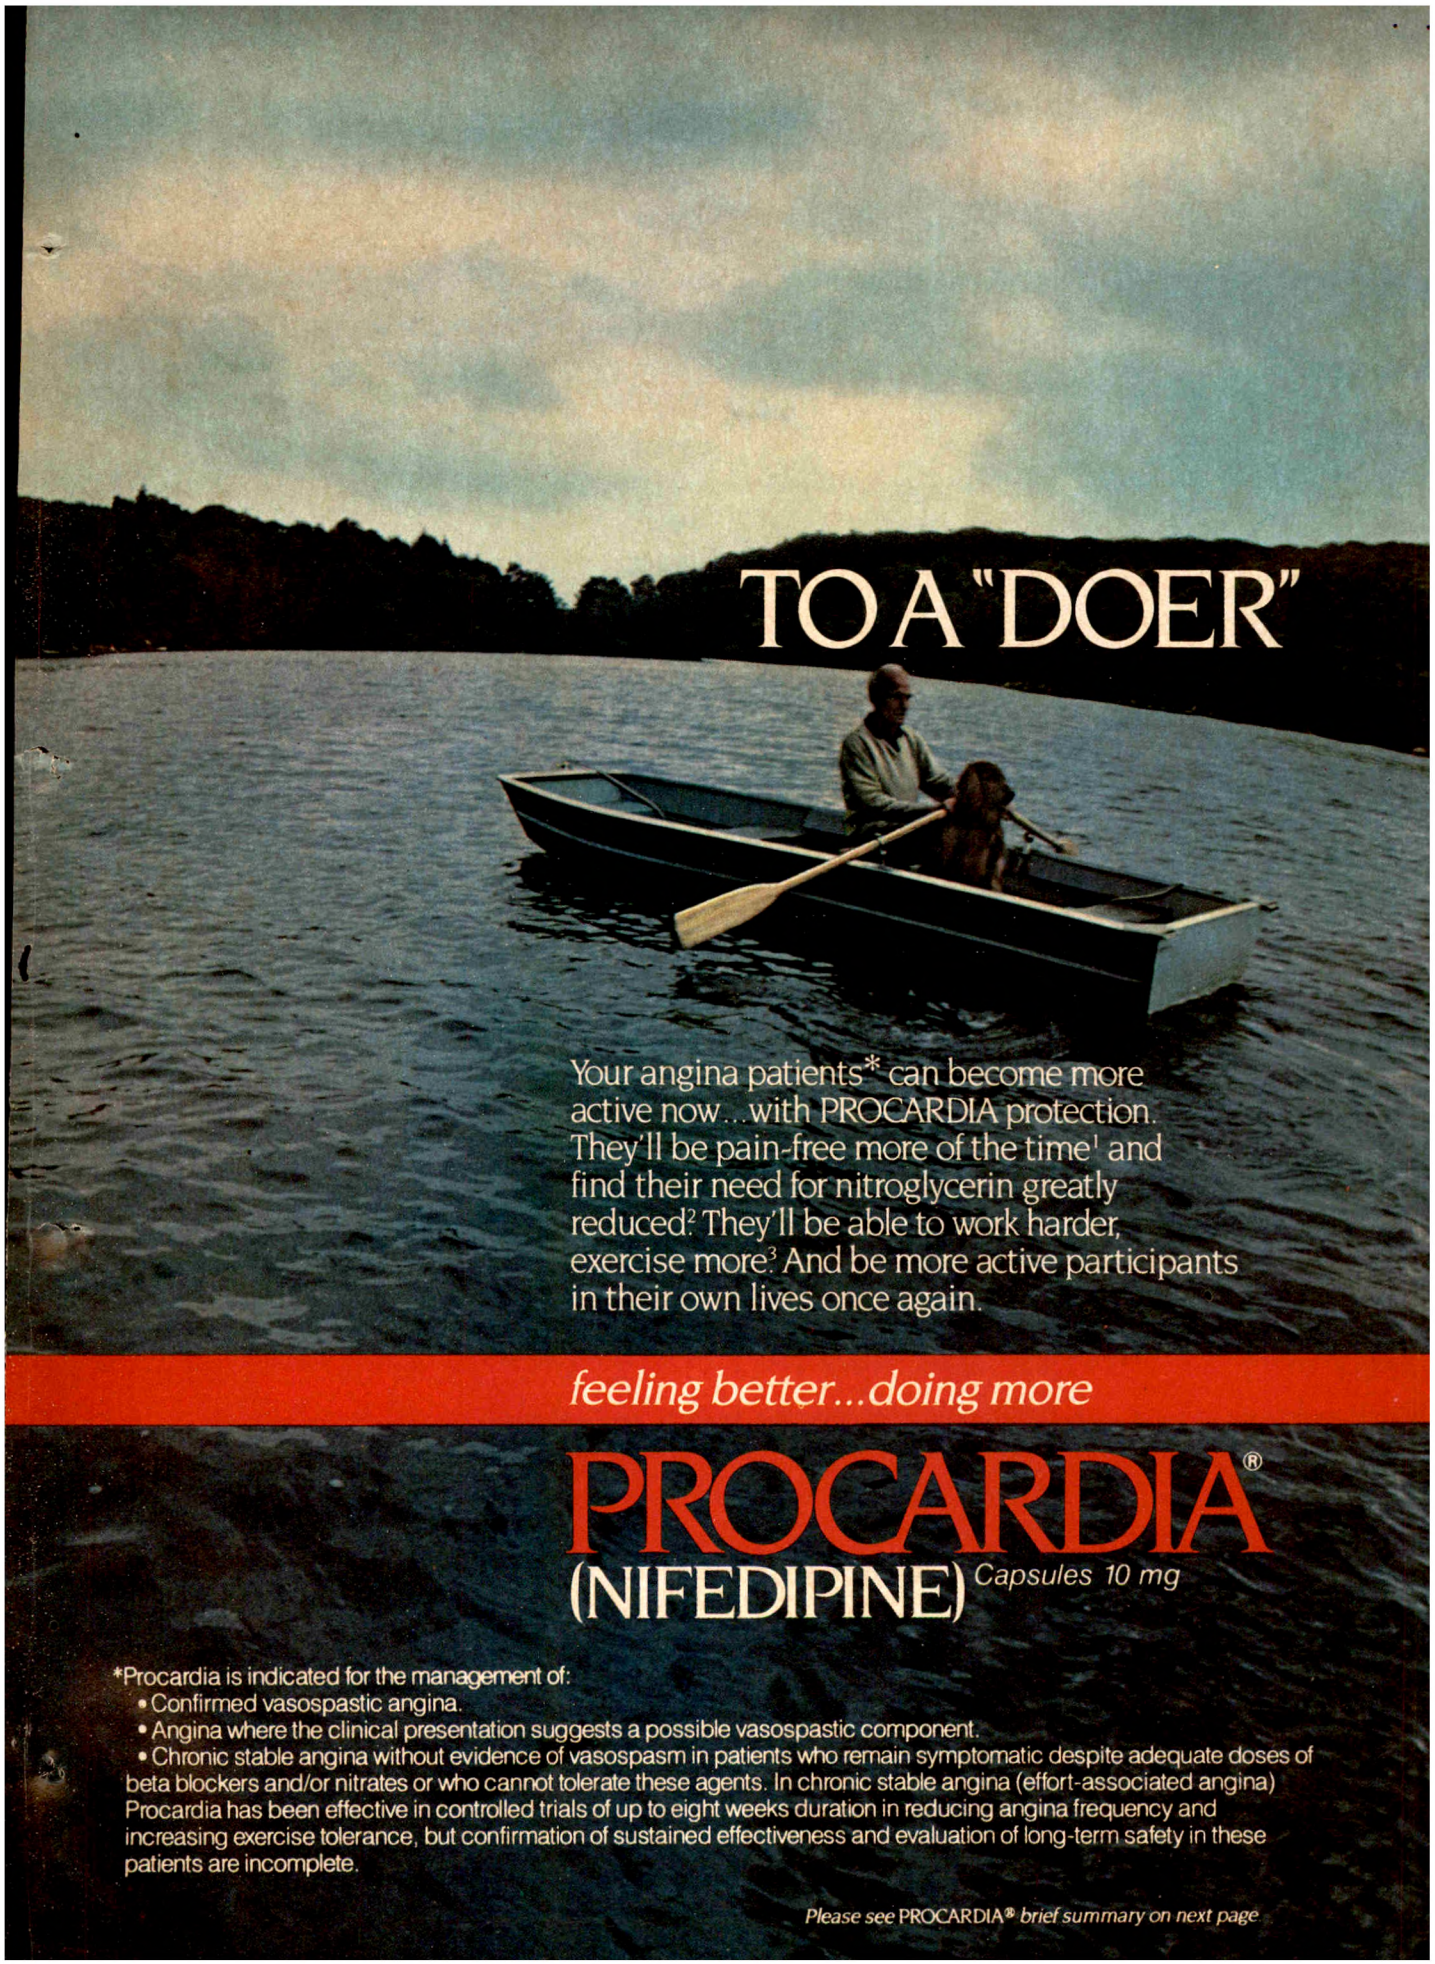
101 Platelet Alpha$_2$ Adrenoreceptors in Chronic Congestive Heart Failure

ROBERT J. WEISS, MICHAEL TOBES, CURTIS E. WERTZ, and CHARLES B. SMITH

Patients with chronic congestive heart failure (CHF) have elevated levels of circulating norepinephrine. The alpha$_2$ adrenoreceptor located on noradrenergic neurons exerts a negative feedback on the release of norepinephrine. This receptor is also located on human blood platelets. The present study compared the specific binding of ^{3}H-clonidine and ^{3}H-yohimbine to alpha$_2$ adrenoreceptors in platelet membranes isolated from normal persons and patients with class I and II and class III and IV CHF. A significant decrease in receptor number was found between normal volunteers and patients with class III and IV CHF (^{3}H-clonidine 25%, $p < 0.05$; ^{3}H-yohimbine 43%, $p < 0.005$). These results support the hypothesis that increased concentrations of circulating norepinephrine lead to a decrease in platelet alpha$_2$ adrenoreceptors. Such changes in receptor number may prove valuable in monitoring therapy of patients with CHF.



© 1983, Pfizer Inc

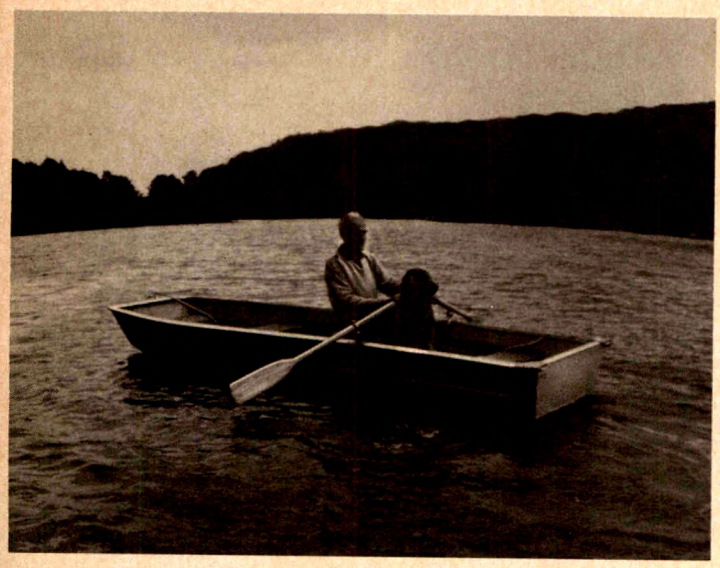


*Procardia is indicated for the management of:

- Confirmed vasospastic angina.
- Angina where the clinical presentation suggests a possible vasospastic component.
- Chronic stable angina without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or nitrates or who cannot tolerate these agents. In chronic stable angina (effort-associated angina) Procardia has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in these patients are incomplete.

Please see PROCARDIA® *brief summary on next page*

feeling better...doing more



PROCARDIA®
(NIFEDIPINE) *Capsules 10 mg*

–Usual effective dosage is 30-60 mg/day

For most patients, titrate over 7 to 14 days, using the patient's blood pressure response, attack frequency, sublingual nitroglycerin intake and activity level as a guide. Titration may be more rapid (e.g., 3 days) if symptoms warrant and the patient is observed closely.

Because Procardia decreases peripheral vascular resistance, careful monitoring of blood pressure during initial administration and titration is suggested. Close observation is especially recommended for patients taking medication known to lower blood pressure.

–Offers a favorable safety profile

Most frequently reported side effects, usually mild, are dizziness or lightheadedness, peripheral edema, nausea, weakness, headache and flushing, each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%.

BRIEF SUMMARY
PROCARDIA® CAPSULES
(nifedipine)
For Oral Use

INDICATIONS AND USAGE: I. Vasospastic Angina: PROCARDIA (nifedipine) is indicated for the management of vasospastic angina confirmed by any of the following criteria: 1) classical pattern of angina at rest accompanied by ST segment elevation, 2) angina or coronary artery spasm provoked by ergonovine, or 3) angiographically demonstrated coronary artery spasm. In those patients who have had angiography, the presence of significant fixed obstructive disease is not incompatible with the diagnosis of vasospastic angina, provided that the above criteria are satisfied. PROCARDIA may also be used where the clinical presentation suggests a possible vasospastic component but where vasospasm has not been confirmed, e.g., where pain has a variable threshold on exertion or in unstable angina where electrocardiographic findings are compatible with intermittent vasospasm, or when angina is refractory to nitrates and/or adequate doses of beta blockers.

II. Chronic Stable Angina (Classical Effort-Associated Angina): PROCARDIA is indicated for the management of chronic stable angina (effort-associated angina) without evidence of vasospasm in patients who remain symptomatic despite adequate doses of beta blockers and/or organic nitrates or who cannot tolerate those agents.

In chronic stable angina (effort-associated angina) PROCARDIA has been effective in controlled trials of up to eight weeks duration in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness and evaluation of long-term safety in those patients are incomplete.

Controlled studies in small numbers of patients suggest concomitant use of PROCARDIA and beta blocking agents may be beneficial in patients with chronic stable angina, but available information is not sufficient to predict with confidence the effects of concurrent treatment, especially in patients with compromised left ventricular function or cardiac conduction abnormalities. When introducing such concomitant therapy, care must be taken to monitor blood pressure closely since severe hypotension can occur from the combined effects of the drugs. (See Warnings.)

CONTRAINDICATIONS: Known hypersensitivity reaction to PROCARDIA.

WARNINGS: Excessive Hypotension: Although in most patients, the hypotensive effect of PROCARDIA is modest and well tolerated, occasional patients have had excessive and poorly tolerated hypotension. These responses have usually occurred during initial titration or at the time of subsequent upward dosage adjustment, and may be more likely in patients on concomitant beta blockers.

Severe hypotension and/or increased fluid volume requirements have been reported in patients receiving PROCARDIA together with a beta blocking agent who underwent coronary artery bypass surgery using high dose fentanyl anesthesia. The interaction with high dose fentanyl appears to be due to the combination of PROCARDIA and a beta blocker, but the possibility that it may occur with PROCARDIA alone, with low doses of fentanyl, in other surgical procedures, or with other narcotic analgesics cannot be ruled out. In PROCARDIA treated patients where surgery using high dose fentanyl anesthesia is contemplated, the physician should be aware of these potential problems and, if the patient's condition permits, sufficient time (at least 36 hours) should be allowed for PROCARDIA to be washed out of the body prior to surgery.

Increased Angina: Occasional patients have developed well documented increased frequency, duration or severity of angina on starting PROCARDIA or at the time of dosage increases. The mechanism of this response is not established but could result from decreased coronary perfusion associated with decreased diastolic pressure with increased heart rate, or from increased demand resulting from increased heart rate alone.

Beta Blocker Withdrawal: Patients recently withdrawn from beta blockers may develop a withdrawal syndrome with increased angina, probably related to increased sensitivity to catecholamines. Initiation of PROCARDIA treatment will not prevent this occurrence and might be expected to exacerbate it by provoking reflex catecholamine release. There have been occasional reports of increased angina in a setting of beta blocker withdrawal and PROCARDIA initiation. It is important to taper beta blockers if possible, rather than stopping them abruptly before beginning PROCARDIA.

Congestive Heart Failure: Rarely, patients, usually receiving a beta blocker, have developed heart failure after beginning PROCARDIA. Patients with tight aortic stenosis may be at greater risk for such an event.

PRECAUTIONS: General: Hypotension: Because PROCARDIA decreases peripheral vascular resistance, careful monitoring of blood pressure during the initial administration and titration of PROCARDIA is suggested. Close observation is especially recommended for patients already taking medications that are known to lower blood pressure. (See Warnings.)

Peripheral edema: Mild to moderate peripheral edema, typically associated with arterial vasodilation and not due to left ventricular dysfunction, occurs in about one in ten patients treated with PROCARDIA. This edema occurs primarily in the lower extremities and usually responds to diuretic therapy. With patients whose angina is complicated by congestive heart failure, care should be taken to differentiate this peripheral edema from the effects of increasing left ventricular dysfunction.

Drug interactions: Beta-adrenergic blocking agents: (See Indications and Warnings.) Experience in over 1400 patients in a non-comparative clinical trial has shown that concomitant administration of PROCARDIA and beta-blocking agents is usually well tolerated, but there have been occasional literature reports suggesting that the combination may increase the likelihood of congestive heart failure, severe hypotension or exacerbation of angina.

Long-acting nitrates: PROCARDIA may be safely co-administered with nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.

Digitalis: Administration of PROCARDIA with digoxin increased digoxin levels in nine of twelve normal volunteers. The average increase was 45%. Another investigator found no increase in digoxin levels in thirteen patients with coronary artery disease. In an uncontrolled study of over two hundred patients with congestive heart failure during which digoxin blood levels were not measured, digitalis toxicity was not observed. Since there have been isolated reports of patients with elevated digoxin levels, it is recommended that digoxin levels be monitored when initiating, adjusting, and discontinuing PROCARDIA to avoid possible over- or under-digitalization.

Carcinogenesis, mutagenesis, impairment of fertility: When given to rats prior to mating, nifedipine caused reduced fertility at a dose approximately 30 times the maximum recommended human dose.

Pregnancy: Category C. Please see full prescribing information with reference to teratogenicity in rats, embryotoxicity in rats, mice and rabbits, and abnormalities in monkeys.

ADVERSE REACTIONS: The most common adverse events include dizziness or light-headedness, peripheral edema, nausea, weakness, headache and flushing each occurring in about 10% of patients, transient hypotension in about 5%, palpitation in about 2% and syncope in about 0.5%. Syncopal episodes did not recur with reduction in the dose of PROCARDIA or concomitant antianginal medication. Additionally, the following have been reported: muscle cramps, nervousness, dyspnea, nasal and chest congestion, diarrhea, constipation, inflammation, joint stiffness, shakiness, sleep disturbances, blurred vision, difficulties in balance, dermatitis, pruritus, urticaria, fever, sweating, chills, and sexual difficulties. Very rarely, introduction of PROCARDIA therapy was associated with an increase in anginal pain, possibly due to associated hypotension.

In addition, more serious adverse events were observed, not readily distinguishable from the natural history of the disease in these patients. It remains possible, however, that some or many of these events were drug related. Myocardial infarction occurred in about 4% of patients and congestive heart failure or pulmonary edema in about 2%. Ventricular arrhythmias or conduction disturbances each occurred in fewer than 0.5% of patients.

Laboratory Tests: Rare, mild to moderate, transient elevations of enzymes such as alkaline phosphatase, CPK, LDH, SGOT, and SGPT have been noted, and a single incident of significantly elevated transaminases and alkaline phosphatase was seen in a patient with a history of gall bladder disease after about eleven months of nifedipine therapy. The relationship to PROCARDIA therapy is uncertain. These laboratory abnormalities have rarely been associated with clinical symptoms. Cholestasis, possibly due to PROCARDIA therapy, has been reported twice in the extensive world literature.

HOW SUPPLIED: Each orange, soft gelatin PROCARDIA CAPSULE contains 10 mg of nifedipine. PROCARDIA CAPSULES are supplied in bottles of 100 (NDC 0069-2600-66), 300 (NDC 0069-2600-72), and unit dose (10x10) (NDC 0069-2600-41). The capsules should be protected from light and moisture and stored at controlled room temperature 59° to 77°F (15° to 25°C) in the manufacturer's original container.

CONGENITAL HEART DISEASE

106 Cardiovascular Effects of Breathing 95 Percent Oxygen in Children With Congenital Heart Dis

ROBERT H. BEEKMAN, ALBERT P. ROCCHINI, and AMNON ROSENTHAL

The hemodynamic effects of breathing 95% oxygen were evaluated in 26 children with congenita ease. After 10 minutes of breathing 95% oxygen, arterial oxygen partial pressure increased from 8 420 ± 89 torr ($p < 0.001$). Cardiac index decreased 21% from 3.96 ± 0.94 to 3.12 ± 0.74 liters/ < 0.001), and stroke index decreased by 11% ($p < 0.001$). A 23% decrease in oxygen consumption (was observed, and oxygen transport decreased from 672.9 ± 179.4 to 600.2 ± 161.3 ml O_2/min/m^2 (Heart rate was kept constant by atrial pacing in a second group of 5 patients; 95% oxygen still signif creased cardiac index, oxygen consumption and stroke index.

112 Altered Baroreceptor Function in Children With Systolic Hypertension After Coarctation Repai

ROBERT H. BEEKMAN, BARRY P. KATZ, CATHERINE MOOREHEAD-STEFFENS, and ALBERT P. ROCCHINI

Baroreceptor function was evaluated in 6 children with repaired coarctation of the aorta with mild ar hypertension and compared with that in 7 normotensive control children. At catheterization, steady moidal baroreceptor function curves relating mean arterial pressure to R-R interval were derived by and decreasing mean arterial pressure with small injections of phenylephrine and nitroprusside. Com control children, the baroreceptor function curves of children with repaired coarctation of the aorta (1 about a higher baseline mean arterial pressure, (2) have a decreased slope, and (3) have a diminished val range.

118 Two-Dimensional Echocardiographic Assessment of Caval and Pulmonary Venous Pathways A Senning Operation

ALVIN J. CHIN, STEPHEN P. SANDERS, ROBERTA G. WILLIAMS, PETER LANG, WILLIAM I. NORWOOD, and ALDO R. CASTANEDA

Two-dimensional echocardiography was performed in 28 patients who had undergone the Senning p Normal values for the caval and pulmonary venous pathway dimensions are established from measur the 18 patients who had no caval or pulmonary venous obstruction or tricuspid regurgitation at cardiac ization. All patients with catheterization-proved caval or pulmonary venous obstruction or severe tricus gitation had echocardiographic dimensions outside this range. Two-dimensional echocardiography ca both quantitative and qualitative information about the caval and pulmonary venous pathways after th procedure.

127 Computer Interpretation of Pediatric Frank Vectorcardiograms in the Evaluation of Congenital Disease

CHRISTIAN R. BROHET, CHRISTIANE DERWAEL-BARCHY, ANNIE ROBERT, ROBERT FESLER, MADY STYNS, LUCIEN A. BRASSEUR, and ANDRÉ VLIERS

A new computer program for automatic interpretation of pediatric vectorcardiograms was tested in a 728 catheterized patients against the true clinical diagnosis determined from hemodynamic and ang data. The diagnostic accuracy (defined as the number of true-positive results plus true-negative resul by the total) was 78% for left ventricular hypertrophy, 79% for right ventricular hypertrophy, 84% fo cular hypertrophy, and 84% for "normal." In general, the accuracy of a positive diagnosis of any ab especially biventricular hypertrophy, was higher in children <2 years of age because of the higher pr of abnormal records in this age group. Thus, although the diagnostic performance of the current vers program was satisfactory, further improvement is expected by making the criteria more adaptable to th tion analyzed.

133 Glucose and Insulin Changes in Infants and Children Undergoing Hypothermic Open-Heart Surg

GEORGE BENZING III, PAUL D. FRANCIS, SAMUEL KAPLAN, JAMES A. HELMSWORTH, and MARK A. SPERLING

This study demonstrates that hyperglycemia, especially in smaller children, is related to excessive e glucose administration intraoperatively and low insulin levels. Since hyperglycemia and resultant osmo sis may give a false impression of cardiorenal performance postoperatively, its prevention has merit. R of glucose in the heart-lung priming solution and in the intraoperative intravenous solutions can preve glycemia.

New CARDIZEM™ (diltiazem HCl)

CALCIUM CHANNEL BLOCKADE

from Marion Laboratories

Potent coronary vasodilation with a distinctive hemodynamic profile

Please see full prescribing information on last pa

30 mg and 60 mg tablets

INCREASES EXERCISE TOLERANCE, REDUCES ANGINAL FREQUENCY WITH A LOW INCIDENCE OF SIDE EFFECTS

CARDIZEM™ (diltiazem HCl) produces changes in cardiovascular hemodynamics and coronary blood flow that are of benefit in myocardial ischemia.

These changes provide effective therapy with a low incidence of side effects.

Indications

(1) Cardizem is indicated in the treatment of angina pectoris due to coronary artery spasm.

(2) Cardizem is indicated in the management of chronic stable angina (classic effort-associated angina) in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents.

ANTIANGINAL MECHANISM OF ACTION

- Produces relaxation of coronary vascular smooth muscle
- Dilates both large and small coronary arteries at drug levels that cause little or no negative inotropic effect
- Produces dose-dependent decreases in peripheral resistance
- Resting heart rate is usually unchanged or slightly reduced

Reduces the pressure/rate product for any given work load in patients with effort-associated angina

© 1983, Marion Laboratories, Inc.

CARDIZEM™ (diltiazem HCl) offers a distinctive profile of effects

(1) Vascular smooth-muscle relaxation with a potent effect on the coronary arteries.[1]

(2) Mild effect on afterload reduction.

(3) In normotensive patients at rest, recommended dosage levels producing coronary vasodilation result in only a mild reduction in diastolic blood pressure and no change in heart rate.

(4) At submaximal exercise, it causes a reduction in heart rate and mean blood pressure compared with placebo, thus reducing myocardial oxygen demand and permitting patients to exercise significantly longer.

(5) Increases coronary blood flow.

(6) Little or no negative inotropic effect at recommended doses while providing a powerful inhibition of coronary artery spasm.

(7) A positive effect on left ventricular function in patients with reduced left ventricular ejection fraction.[2]

(8) Increases ejection fraction at both submaximal and maximal exercise. Exercise ejection fraction is especially increased in patients with poor ventricular function.[3]

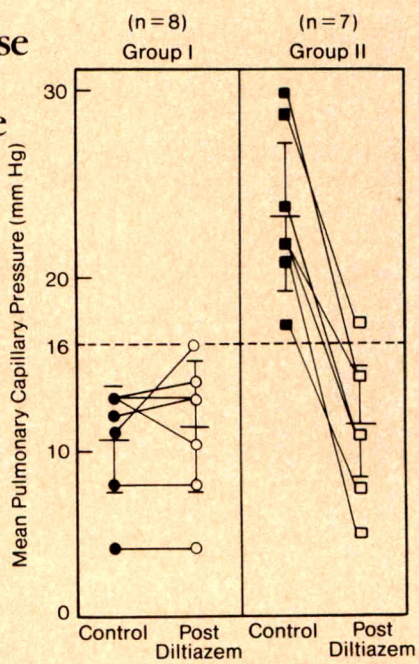
While Cardizem tends to prolong AV conduction,* only rarely has there been an increase in PR intervals outside of normal limits.

*See Contraindications and Warnings.

CARDIZEM™ (diltiazem HCl) tends to normalize stress-induced increases in pulmonary capillary pressure (PCP)

The effect of a single 120-mg† dose of Cardizem was evaluated on symptom-limited upright exercise in 15 patients with effort angina.[4]

†It should be noted that this study employed a single 120-mg dose of diltiazem for hemodynamic measurement purposes. The approved maximum dose for Cardizem is 240 mg given in divided doses, three to four times daily.



CHANGE IN FILLING PRESSURE AT MAXIMAL EXERCISE[4]

Patients with control PCPs in normal range at maximal exercise showed little change in these values following diltiazem (Group I). Patients with markedly elevated control PCPs at maximal exercise (>16 mm Hg) showed dramatic reductions in these values following diltiazem (Group II).

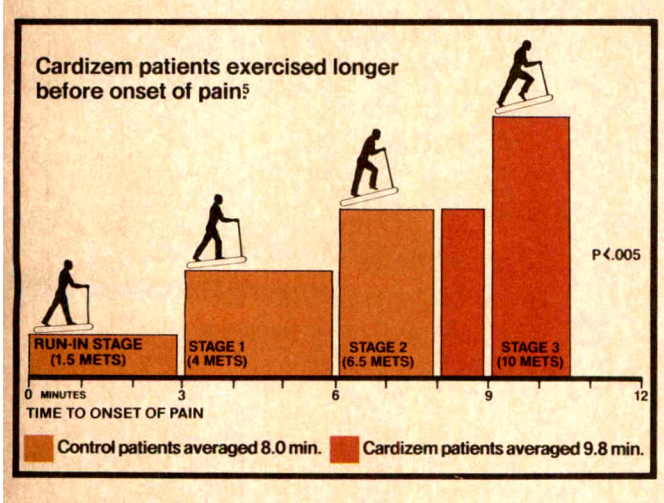
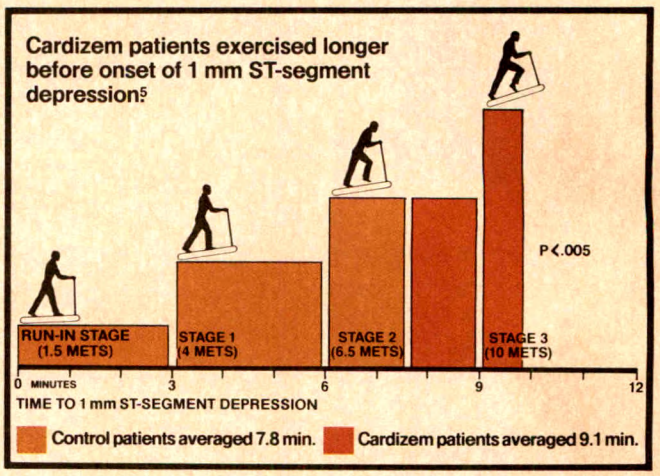
EXCELLENT CLINICAL RESPONSE TO CARDIZEM™ (diltiazem HCl) IN THE MANAGEMENT OF CLASSIC EFFORT ANGINA

CARDIZEM™ (diltiazem HCl) allows angina patients to significantly prolong exercise tolerance, even in demanding Bruce protocol exercise tests[5] (n=15)*





Protocol:

A Bruce protocol with a run-in stage was used. Each stage lasts three minutes.

Succeeding stages represent such an increase in speed and slant of the treadmill that each minute spent in a succeeding stage represents a highly significant increase in metabolic equivalents (METS). For example, METS expenditure in run-in stage of the protocol (0 to 3 min) is 1.5. METS expenditure of stage 1 (3 to 6 min) is 4.0. Stage 2 (6 to 9 min) expenditure is 6.5, and stage 3 (9 to 12 min) is 10.

The study[5,6] was double-blind, randomized, triple cross-over comparing diltiazem with placebo, lasting 7 weeks.

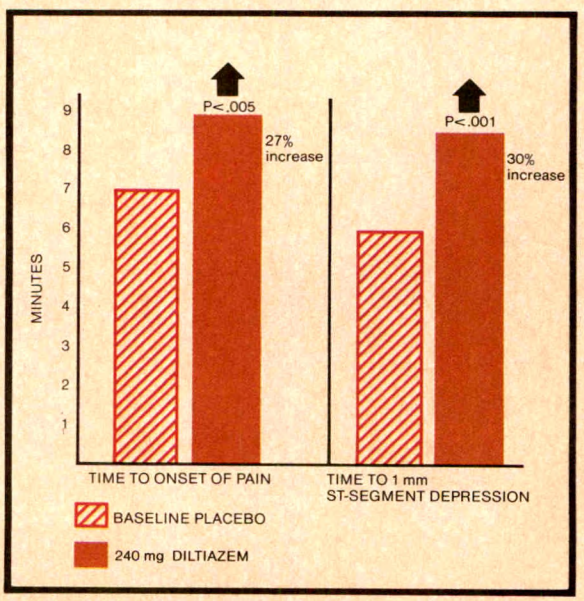
*This study is a report from one center in a multicenter study.

CARDIZEM™ (diltiazem HCl) produced marked angina improvement in multicenter study[6]

- 27% increase in time to onset of pain
- 30% increase in time to ST-segment depression



RESULTS OF 57 PATIENTS EVALUATED IN A MULTICENTER STUDY.[6]

CARDIZEM™ (diltiazem HCl) PRODUCED SIGNIFICANT DECREASE IN EFFORT ANGINA ATTACKS COMPARED WITH PLACEBO IN 63-PATIENT DIARY STUDY[7]

Cardizem therapy resulted in a mean reduction of 5.3 attacks per week during weeks 7 and 8, compared with a mean reduction with placebo of 2.0 attacks per week.

During weeks 9 and 10, Cardizem therapy resulted in a mean reduction of approximately 5.9 attacks per week compared with a mean reduction of 2.5 attacks per week with placebo.

41% TO 68% REDUCTION IN FREQUENCY OF PRINZMETAL'S VARIANT ANGINA ATTACKS WITH CARDIZEM™ (diltiazem HCl)[8]

Mean attack rate during 120-mg/day dosage period was reduced 41% from baseline period. In 240-mg/day phase, decrease with Cardizem was 68%. This shows a positive dose-related response.

75% reduction in attack rate reported in 13-patient, cross-over, placebo-controlled study[1]

71% reduction in attack rate reported in 11-patient, cross-over, placebo-controlled study[9]

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

LOW INCIDENCE OF SIDE EFFECTS WITH CARDIZEM™ (diltiazem HCl)

In placebo-controlled trials conducted in the United States, the incidence of adverse reactions reported during Cardizem therapy was not greater than that reported during placebo therapy.

Those adverse reactions reported most frequently with CARDIZEM™ (diltiazem HCl) have been:

- Nausea 2.7%
- Swelling/edema 2.4%
- Arrhythmia 2.0%
- Headache 2.0%
- Rash 1.8%
- Fatigue 1.1%

In many cases, the relationship to Cardizem has not been established.

Other reactions infrequently reported (<1.0%) during supervised trials were:

- Cardiovascular: Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart
- Central Nervous System: Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations
- Gastrointestinal: Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis
- Dermatologic: Pruritus, petechiae, urticaria
- Other: Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain

Of those adverse reactions reported, the most severe were:
A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of Cardizem.

Experience in 959 patients taking oral doses of Cardizem resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

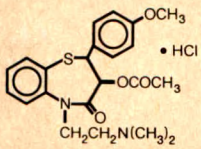
In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during Cardizem therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

CARDIOMYOPATHY

137 Cardiac Amyloidosis Causing Cardiac Dysfunction: Analysis of 54 Necropsy Patients

WILLIAM C. ROBERTS and BRUCE F. WALLER

Clinical and morphologic findings are described in 54 necropsy patients (32 men [59%]) aged 21 to 97 years (mean 64) with cardiac amyloid deposits extensive enough to cause fatal cardiac dysfunction. Chronic congestive heart failure (CHF) was present in 46 (85%). The duration of CHF, known in 39 patients, ranged from 1 to 108 months (mean 18) and lasted ≤12 months in 25 patients (64%). All 8 patients without CHF died suddenly and unexpectedly. Systemic arterial pressures were recorded in the last 3 months of life in 43 patients; the peak indirect systolic pressure was ≤130 mm Hg and the diastolic pressure <90 mm Hg in all. Electrocardiograms, recorded in the last 6 months of life in 40 patients, were abnormal in each, revealing low voltage in 35 (63%); "myocardial infarction pattern" in 33 (83%); abnormal QRS axis in 29 (73%); arrhythmias in 29 (73%); first-, second-, or third-degree heart block in 28 (45%); and complete bundle branch block in 7 (18%). In 30 patients, the QRS amplitude in all 12 leads was measured. In the 15 men it ranged from 60 to 197 mm (mean 99) (10 mm = 1 mV) and in the 15 women from 58 to 199 mm (mean 109). The diagnosis of amyloidosis was established by biopsy of noncardiac organs or tissues during life in only 18 patients (33%). During life the condition simulated hypertrophic cardiomyopathy in 5 patients, constrictive pericardial disease in 3, and coronary heart disease (because of angina pectoris) in 4.

147 Cardiac Thrombosis and Thromboembolism in Chronic Chagas' Heart Disease

J. SAMUEL M. OLIVEIRA, ROSALLY R. CORREA DE ARAUJO, MARCOS A. NAVARRO, and GERSON MUCCILLO

A retrospective study of Chagas' heart disease was carried out by a review of 1,355 autopsy reports, with special reference to cardiac thrombus and thromboembolic phenomena. The incidence of cardiac thrombus was higher in cases of heart failure (36%) than in cases of sudden death (15%), higher in heavier hearts, and unrelated to age or sex. The left- and right-sided cardiac chambers were equally affected by thrombus. Endocarditis and blood stasis were considered important factors in the pathogenesis of cardiac thrombosis. Thromboembolic phenomena were more common in the systemic circulation but caused relatively more deaths by pulmonary embolism. Fourteen percent of the patients with thromboembolic phenomena actually died from them. Patients with multiple thromboembolic phenomena have a higher risk of death from embolism. Cardiac thrombosis or thromboembolic phenomena, or both, were present in 44% of the cases studied. Prophylactic measures should be taken for these important complications of Chagas' heart disease.

MISCELLANEOUS TOPICS

152 Aortic Valve Closure and Cardiac Vibrations in the Genesis of the Second Heart Sound

MARKKU KUPARI

Simultaneous M-mode echocardiograms and external phonocardiograms were recorded in 15 healthy subjects to evaluate the genesis of the second heart sound. The onset of the second sound was found synchronous with the coaptation of the aortic valve cusps and a sharp vibration on the aortic wall. The closed value was oscillating for 30 to 45 ms after the coaptation of the cusps. Magnified echocardiographic studies of the interventricular septum revealed a consistent, momentary quiver across the septal myocardium a mean of 4 ms after the onset of the second sound. In most subjects, a transient myocardial vibration was observed in temporal association with the first heart sound as well. These observations suggest that aortic valve closure initiates the production of the second heart sound; the main audible component results, however, from vibrations in the cardiac structures after valve closure.

155 Analysis of the Amount of Tricuspid Valve Anular Dilatation Required to Produce Functional Tricuspid Regurgitation

JOSE L. UBAGO, ALVARO FIGUEROA, ALBERTO OCHOTECO, THIERRY COLMAN, RAFAEL M. DURAN, and CARLOS G. DURAN

In an attempt to determine the critical anular dilatation required for functional tricuspid regurgitation (TR) and the role of the systolic anular shortening in the severity of this regurgitation, 67 patients with right ventriculography were studied. These patients were classified into Group I, control, and Group II, patients with rheumatic valvular disease. The 55 Group II patients were subclassified into Group IIa, patients without TR, Group IIb, patients with mild TR, and Group IIc, patients with moderate to severe TR. The angiographic maximal early systolic and minimal end-systolic diameters were measured. The shortening of the tricuspid anulus was expressed as percent reduction of the maximal diameter. The average maximal diameter in the control group was 21 ± 2 mm/m^2 and the minimal diameter 15 ± 2; the percent shortening was 30 ± 7%. The rheumatic patients had a larger maximal diameter than the control group. Anular shortening was reduced only in the group with moderate to severe

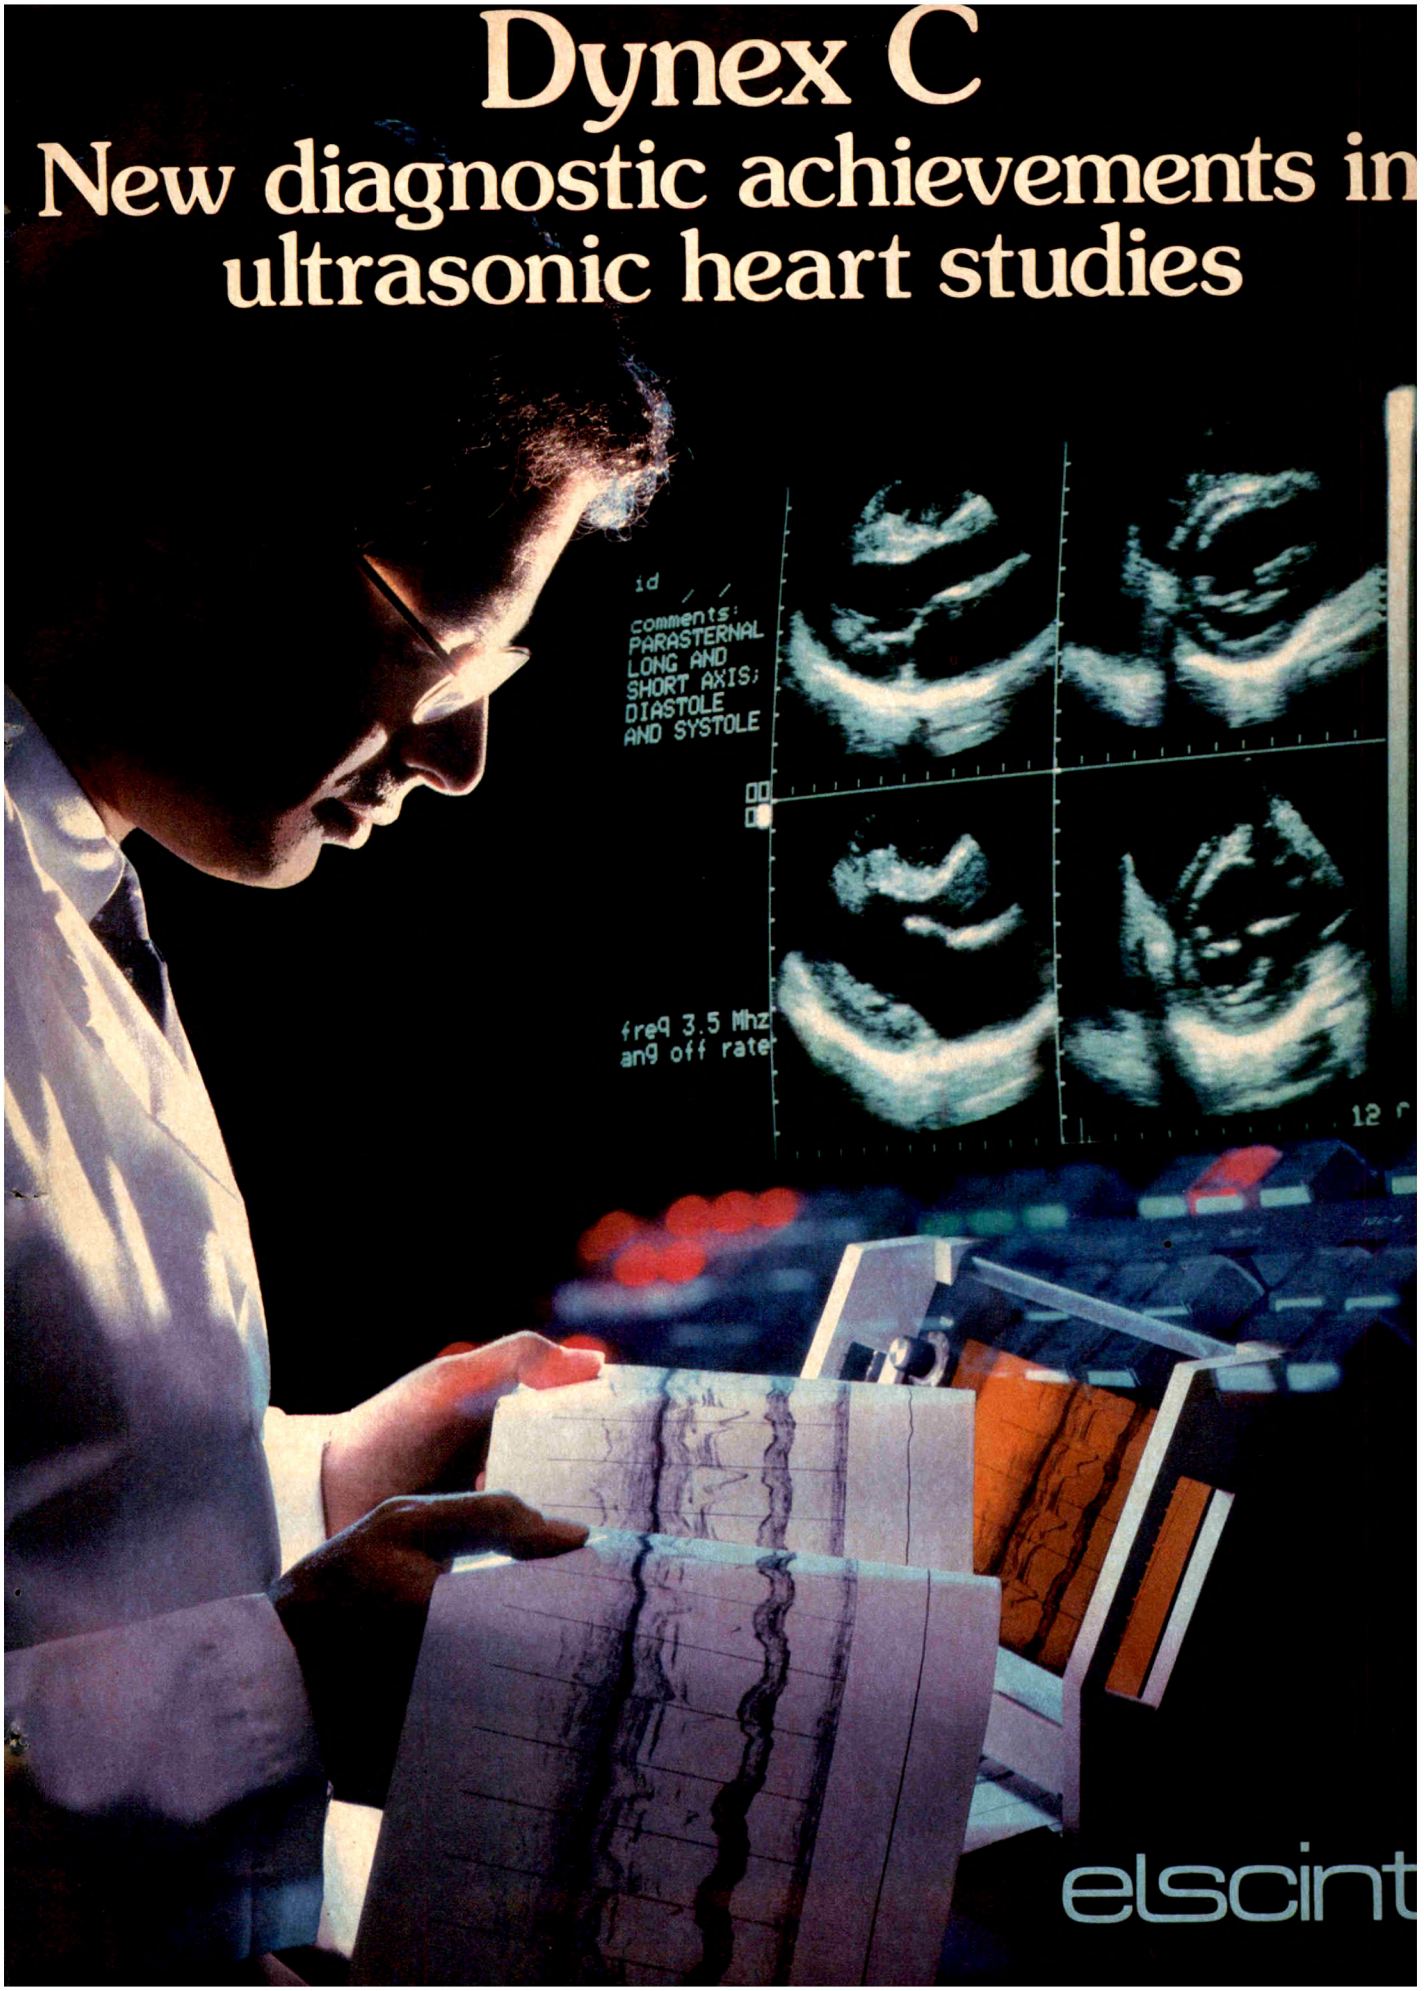
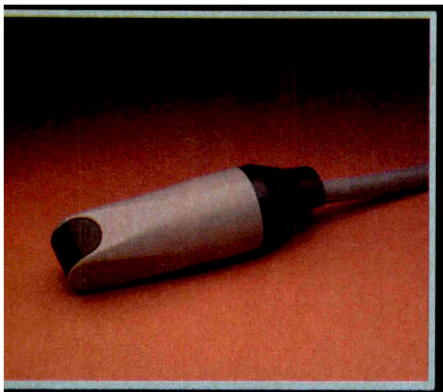
Dynex C

New diagnostic achievements in ultrasonic heart studies



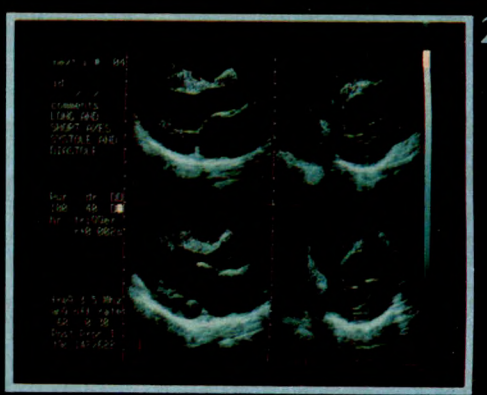
elscint



1. Dynex/C Probes: Out in Front

Dynex/C 3.5 and 5 MHz mechanical sector probes, feature four unique characteristics which put them far ahead of the field:

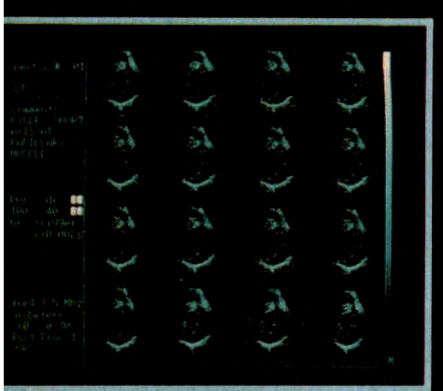
- □ Inherently fine spatial resolution due to computer controlled automatic line density optimization.
- □ An extremely wide, continuously variable 15-105° sector angle.
- □ Exceptionally fast frame rates: more than 70 frames per second, continuously variable.
- □ A continuously adjustable offset angle ranging from 0-45°.



2

Multiformatting: Comparison at a Glance

Dynex/C's ability to display four images simultaneously gives the cardiologist an incomparable diagnostic tool. He may compare four identical views taken over a period of time, or study four different images acquired during the same examination — for example, tomographic sections along the long and short axes, at end systole and end diastole.



3. CCRM™ — Cardiac Cycle Review Mode

The CCRM is an exclusive Dynex/C feature for viewing fast sequential 2-D cardiac events, or a complete heart cycle.

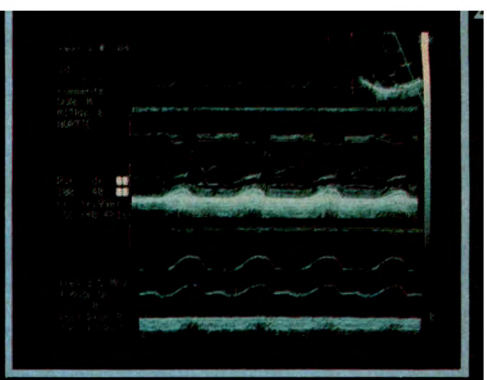
Cardiac scanning at an extremely fast frame rate stops at a pre-selected ECG point. The last 16 frames acquired are stored in memory, and may be reviewed separately or in closed-loop cine mode at a user-selected speed.

elscint

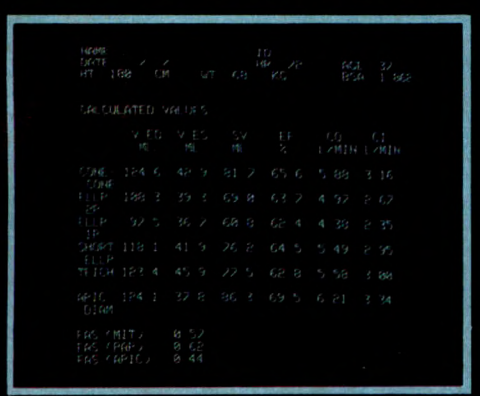
4. M-Mode Display Capabilities

Dynex/C's M-mode has two features of truly exceptional value to the cardiologist:

1. Simultaneously with normal M-mode, Dynex/C displays a two-dimensional image with M-mode position precisely defined by a cursor.
2. *Dual M-mode:* simultaneous display of two M-modes from different cardiac regions, both synchronized with a user-selected ECG or PCG point.



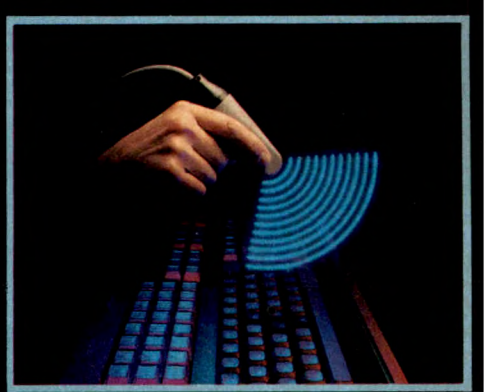
5



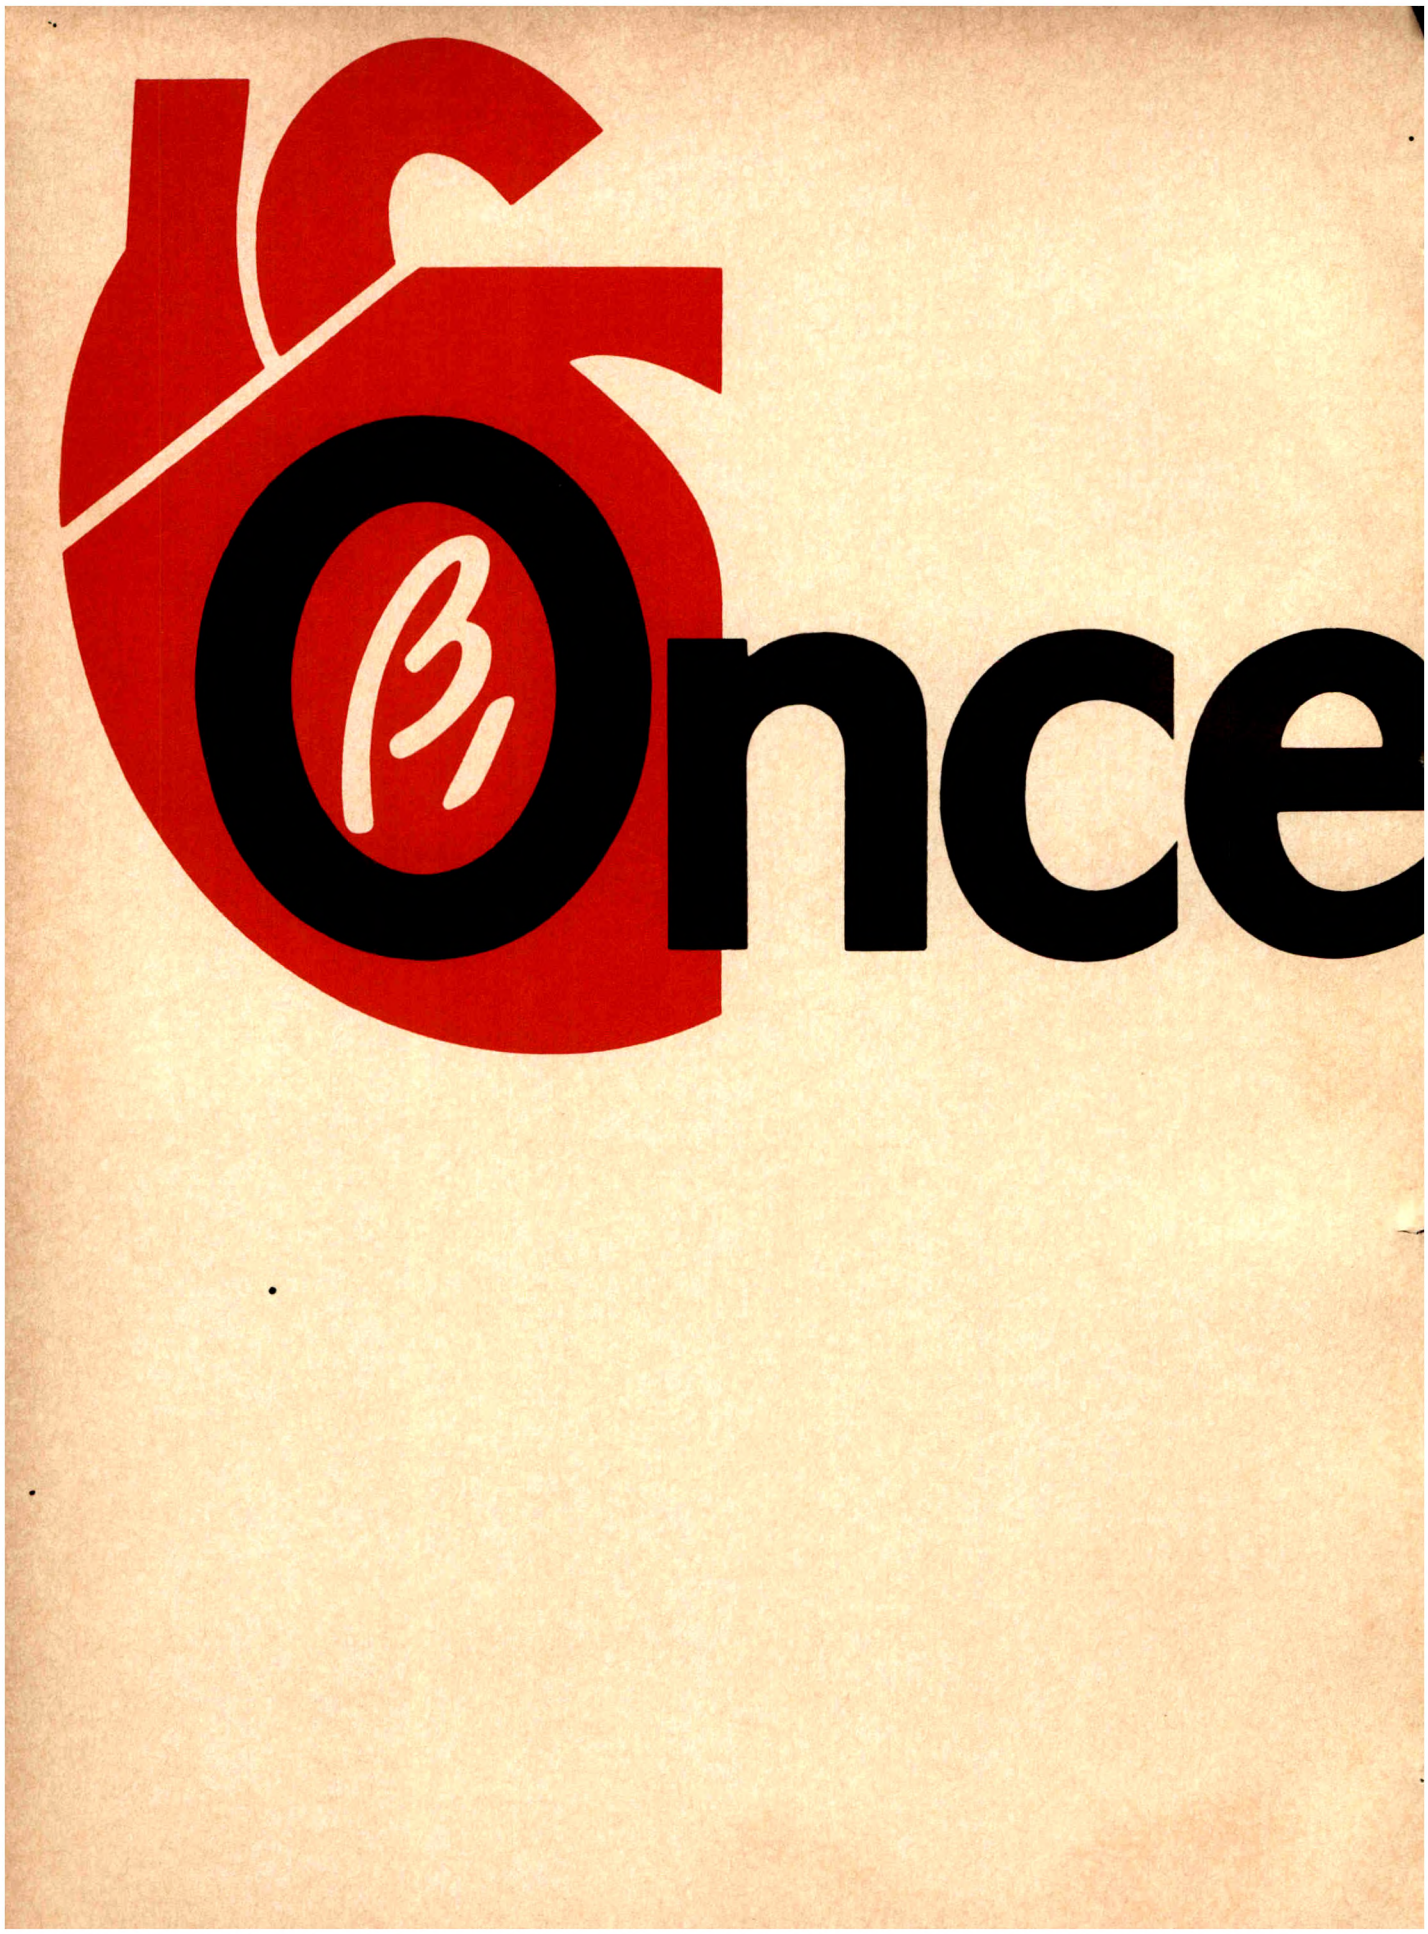
5. Advanced Cardiac Data Calculations

Dynex/C's comprehensive software and powerful computer enable precise measurements and on-line calculations of many vital cardiac parameters. Frozen M-mode displays give aortic and mitral valve stroke volume and flow, pre-ejection/ejection time ratio, fractional IVS shortening, and over 30 other values.

Left ventricular volume is determined from 2-D images using *six* advanced calculation methods. Stroke volume, cardiac output, ejection fraction, cardiac index and more, are computed and displayed.



Dynex C: we speak from a position



Once

Now...

Once-a-day antihypertensive efficacy confirmed worldwide

Studies done in the U.S.A., England, Scandinavia and other parts of Europe and Asia have shown that once-a-day dosage of metoprolol significantly reduced both systolic and diastolic pressure.[1-11]

-a-day

cardioselective*

Lopressor®

metoprolol tartrate

New dosage schedule: To start, 100 mg once-a-day, or in divided doses.

Lower doses (especially 100 mg) may not maintain full effect at end of 24-hour period. Measure BP near end of dosing interval, adjust to larger or more frequent dosage if needed.

*exerts a relative preference for beta-one receptors; this preference is not absolute.

Contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure.

Please turn page for brief Prescribing Information.

Geigy

Now more convenient than ever in once-a-day dosage

Lopressor®
metoprolol tartrate

An antihypertensive beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information.

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

perthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

C83-16 (Rev. 5/83) 536-5761-A

GEIGY Pharmaceuticals
Division of CIBA-GEIGY Corporation
Ardsley, New York 10502

TR and was preserved in the other groups, including those with mild TR. The critical diameter was determined to be between the maximal diameter in the rheumatic patients without TR and the minimal diameter in the patients with moderate to severe TR, or 27 mm/m^2. Thus this easily measured variable can determine the presence and significance of functional TR, adding objectivity to the angiographic diagnosis of TR.

159 Effect of Pericardiocentesis on Right and Left Ventricular Function and Volumes in Pericardial Effusion

DANTE E. MANYARI, WILLIAM J. KOSTUK, and PAUL PURVES

Radionuclide techniques were used to measure right and left ventricular ejection fraction and volume changes produced by pericardiocentesis in patients with pericardial effusion. During 14 studies, mean right and left ventricular ejection fractions did not change significantly after removal of 527 ml (range 140 to 1,100) of pericardial fluid. Similar ejection fraction changes were observed in 4 subgroups: patients with and without cardiac tamponade and patients with normal and subnormal left ventricular function. End-diastolic and end-systolic volumes increased significantly after pericardiocentesis in both ventricles, but these changes were comparatively larger in the right ventricle. Volume changes were more marked in patients with than in those without cardiac tamponade. Thus, hemodynamic and clinical improvement after pericardiocentesis may be related only to an increase in stroke volume. The ejection fraction, a measure of myocardial contractility, remained unchanged.

163 Acute Effects of Phlebotomy on Right Ventricular Size and Performance in Polycythemic Patients With Chronic Obstructive Pulmonary Disease

ALLAN D. ERICKSON, WILLIAM A. GOLDEN, BEN C. CLAUNCH, WALTER E. DONAT, and JOHN T. KAEMMERLEN

Equilibrium radionuclide angiography was performed in 10 patients with severe chronic obstructive pulmonary disease and erythrocytosis before and immediately after phlebotomy. The mean right ventricular ejection fraction was abnormal before (0.38) but not after (0.43) phlebotomy and the increase was highly significant ($p < 0.001$). Similarly, the right ventricular end-diastolic area, a reflection of ventricular volume, decreased significantly, from 588 to 505 pixels ($p < 0.02$). No significant changes occurred on the left side; cardiac output was well maintained. If afterload was unchanged, as has been reported, these data are consistent with the hypothesis that a normalization in preload shifts the Starling curve, resulting in improved right ventricular performance with preservation of cardiac output.

167 Left Ventricular Performance During Exercise: Response of Ear Densitogram Derivative

BRUCE G. HAFFTY, TETSURO SUGIURA, NANCY E. O'HARE, and DAVID H. SPODICK

The peak ear densitogram derivative slowly increased throughout exercise in normal subjects to 2 minutes of recovery. In patients with coronary artery disease, the peak derivative rapidly increased to only 1 minute of exercise. Percent changes from control were significantly different, as were group differences at 1 minute ($p < 0.01$) and 4 minutes of exercise ($p < 0.05$) and 2 minutes after exercise ($p < 0.05$).

172 Effect of Cimetidine on the Pharmacokinetics and Pharmacodynamics of Quinidine

BRIAN G. HARDY, ISTVAN T. ZADOR, LAWRENCE GOLDEN, DAVID LALKA, and JEROME J. SCHENTAG

The influence of cimetidine on the disposition and pharmacodynamic effects of a single oral dose of quinidine was evaluated in 6 normal volunteers. After cimetidine pretreatment (1.2 g/day for 7 days), statistically significant increases in quinidine mean elimination half-life of 55% (range 30 to 109), peak plasma concentration of 21% (range 8 to 61), and time to peak concentration of 33% (range 8 to 118) were observed. An overall decrease in mean apparent oral clearance of 37% (range 23 to 49) resulted, without any significant changes in plasma protein binding or urinary excretion of unchanged drug. Cimetidine-induced changes in the pharmacokinetics of quinidine were accompanied by increases in simultaneously measured electrocardiographic effect variables. Changes in the Q-T interval, rate-corrected Q-T, QRS, and R-R intervals after a single dose of quinidine sulfate (400 mg) were significant. Treatment with cimetidine potentiated these pharmacodynamic responses, but failed to achieve significant differences from quinidine alone.

EXPERIMENTAL STUDIES

177 Relation Between Functional Response to Nitroglycerin and Extent of Myocardial Necrosis in Dogs: Mapping of the Left Ventricle by 2-Dimensional Echocardiography

KEICHO SHIMOURA, SAMUEL MEERBAUM, TATSUO SAKAMAKI, SHUJI KONDO, MICHAEL C. FISHBEIN, JACOB Y-RIT, CHUWA TEI, PRAVIN M. SHAH, and ELIOT CORDAY

Segmental 2-dimensional (2-D) echocardiographic study of left ventricular (LV) segmental response to discrete nitroglycerin infusion was performed in closed-chest dogs during acute occlusion of the left anterior descending

Say Goodbye to CINEGRAM®..

SAY HELLO TO CINEREX™

Agfa-Gevaert Rex has changed the name of its Cine Imaging Systems Division and trademark...and here's what that change means to you:

1. It reinforces the relationship between Agfa-Gevaert Rex and our Cine Imaging Systems Division.

2. It means that the cine imaging products you have so overwhelmingly accepted will eventually all have new labels, but will be exactly the same in all other respects...the industry's best.

3. The Imaging Specialists you have been working with will continue to serve you as before, and our technical support, quality management and training programs will remain the industry's standard.

4. It means that Agfa-Gevaert, one of the world's leading manufacturers of photographic and radiographic products, will be introducing new CINEREX™ products for cardiologists and cath labs.

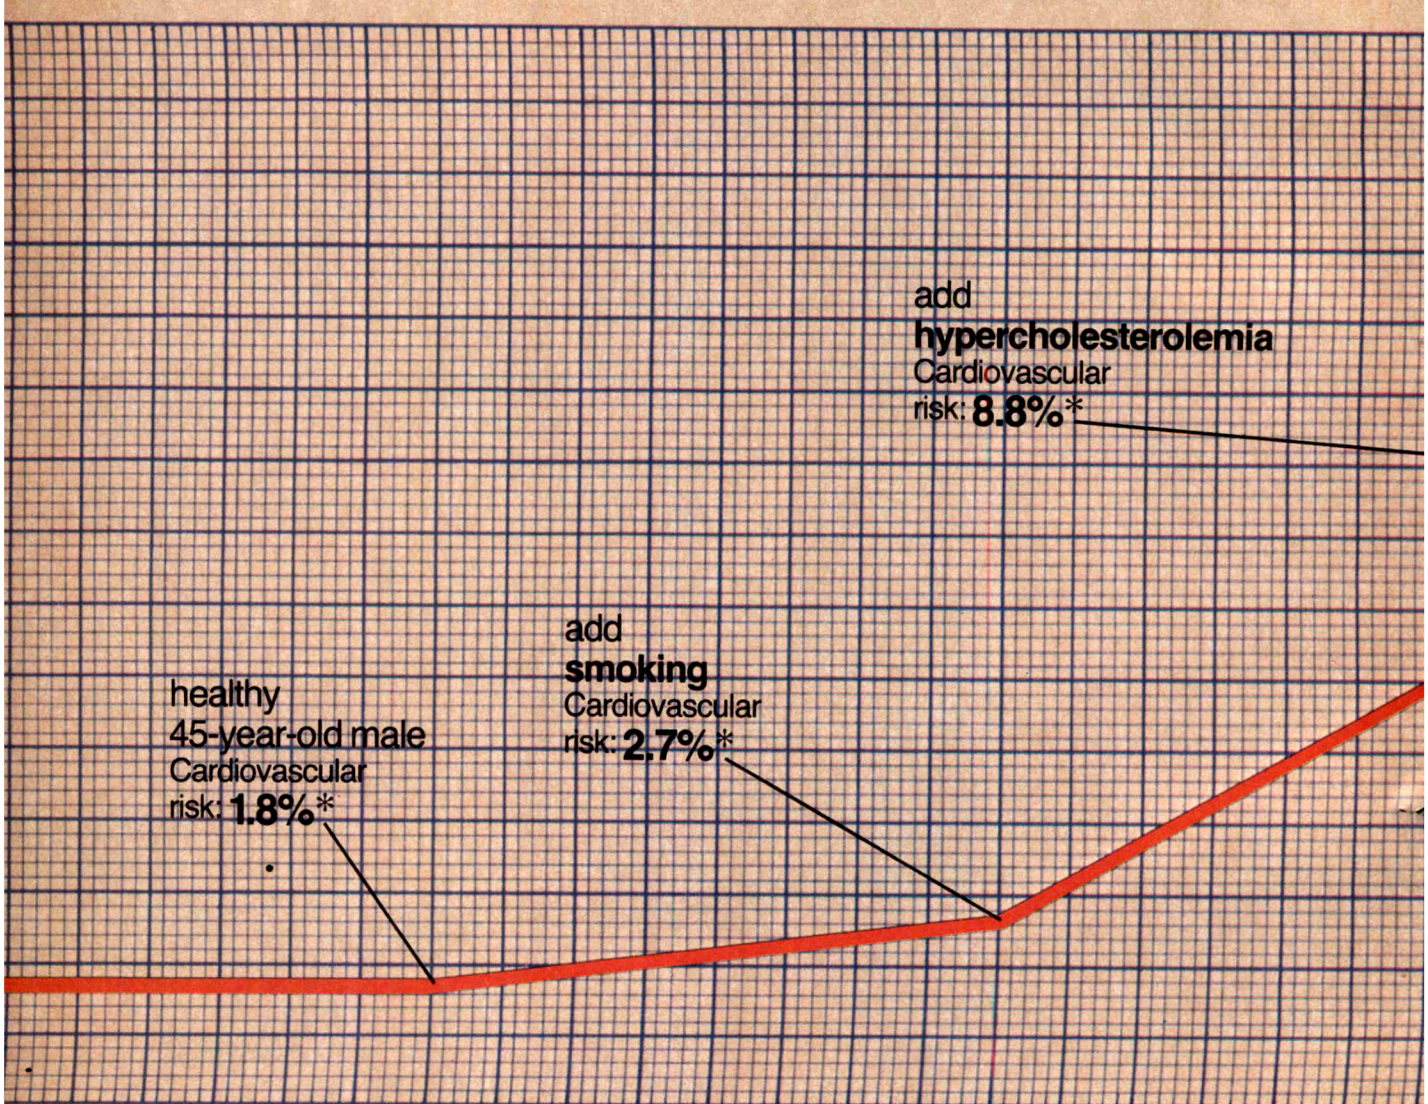
5. And...although you may be seeing both our old brand name and our new one on your shelves for a while, soon it will all be CINEREX.

So start thinking CINEREX...but don't be embarrassed if you forget and call us by our old name. Good things are hard to forget.

CINEREX™

CINEREX IMAGING SYSTEMS
Division of Agfa-Gevaert Rex, Inc.
925 Westchester Avenue, P.O. Box 190
White Plains, New York 10602
(914) 682-5688

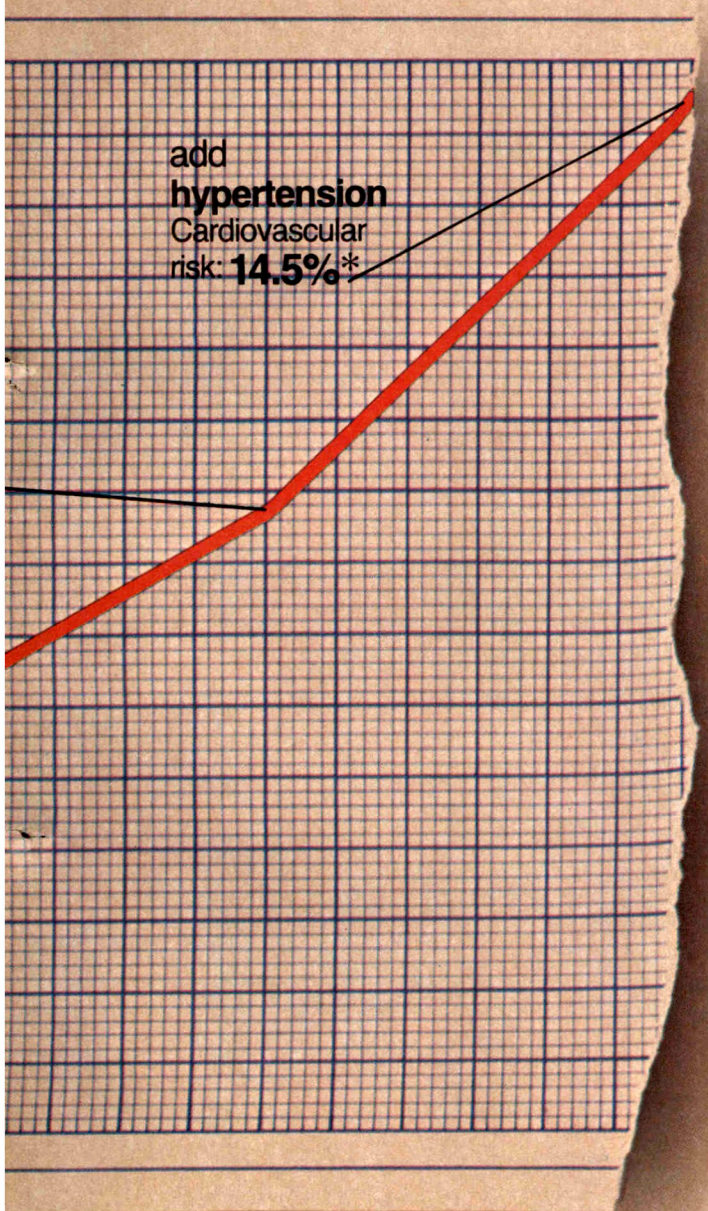
In hypertensive patients:



Other risk factors in CHD are diabetes, obesity, lack of exercise, stress, heredity, sex, age, race.

*Percent equals chances in 100 of developing

Consider the Risks



- When selecting antihypertensive therapy, clinical consideration should be given to the effects of the specific drug on coronary risk factors. Blood pressure control should be achieved without adversely affecting blood lipids.

Minipress Effectively Controls Hypertension Without Adverse Effect on Blood Lipids†

- Minipress effectively treats hypertension. Patients have benefited from the effectiveness of Minipress in over 5 years of clinical use in this country.[1-5]

- Minipress has been shown not to have an adverse effect on blood lipids, according to The Oslo Study and other reports.[6-9] Because Minipress lowers high blood pressure and does not produce lipid changes which are potentially atherogenic, it provides your patient with a net reduction in risk.

†Minipress is not indicated for the treatment of hyperlipidemia.

Please see Minipress brief summary on following page.

Minipress®
(prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

© 1982, Pfizer Inc.

Minipress® (prazosin HCl) Capsules 1 mg, 2 mg, 5 mg

B.I.D. Dosage Convenience

BRIEF SUMMARY
MINIPRESS® (prazosin hydrochloride) CAPSULES *For Oral Use*
INDICATIONS: MINIPRESS® (prazosin hydrochloride) is indicated in the treatment of hypertension. As an antihypertensive drug, it is mild to moderate in activity. It can be used as the initial agent or it may be employed in a general treatment program in conjunction with a diuretic and/or other antihypertensive drugs as needed for proper patient response.
WARNINGS: MINIPRESS (prazosin hydrochloride) may cause syncope with sudden loss of consciousness. In most cases this is believed to be due to an excessive postural hypotensive effect, although occasionally the syncopal episode has been preceded by a bout of severe tachycardia with heart rates of 120-160 beats per minute. Syncopal episodes have usually occurred within 30 to 90 minutes of the initial dose of the drug; occasionally they have been reported in association with rapid dosage increases or the introduction of another antihypertensive drug into the regimen of a patient taking high doses of MINIPRESS (prazosin hydrochloride). The incidence of syncopal episodes is approximately 1% in patients given an initial dose of 2 mg or greater. Clinical trials conducted during the investigational phase of this drug suggest that syncopal episodes can be minimized by limiting the initial dose of the drug to 1 mg, by subsequently increasing the dosage slowly, and by introducing any additional antihypertensive drugs into the patient's regimen with caution (see DOSAGE AND ADMINISTRATION). Hypotension may develop in patients given MINIPRESS who are also receiving a beta-blocker such as propranolol.

If syncope occurs, the patient should be placed in the recumbent position and treated supportively as necessary. This adverse effect is self-limiting and in most cases does not recur after the initial period of therapy or during subsequent dose titration.

Patients should always be started on the 1 mg capsules of MINIPRESS (prazosin hydrochloride). The 2 and 5 mg capsules are not indicated for initial therapy.

More common than loss of consciousness are the symptoms often associated with lowering of the blood pressure, namely, dizziness and lightheadedness. The patient should be cautioned about these possible adverse effects and advised what measures to take should they develop. The patient should also be cautioned to avoid situations where injury could result should syncope occur during the initiation of MINIPRESS (prazosin hydrochloride) therapy.

Usage in Pregnancy: Although no teratogenic effects were seen in animal testing, the safety of MINIPRESS (prazosin hydrochloride) in pregnancy has not been established. MINIPRESS (prazosin hydrochloride) is not recommended in pregnant women unless the potential benefit outweighs potential risk to mother and fetus.

Usage in Children: No clinical experience is available with the use of MINIPRESS (prazosin hydrochloride) in children.

ADVERSE REACTIONS: The most common reactions associated with MINIPRESS (prazosin hydrochloride) therapy are: dizziness 10.3%, headache 7.8%, drowsiness 7.6%, lack of energy 6.9%, weakness 6.5%, palpitations 5.3%, and nausea 4.9%. In most instances side effects have disappeared with continued therapy or have been tolerated with no decrease in dose of drug.

The following reactions have been associated with MINIPRESS (prazosin hydrochloride), some of them rarely. (In some instances exact causal relationships have not been established.)

Gastrointestinal: vomiting, diarrhea, constipation, abdominal discomfort and/or pain.

Cardiovascular: edema, dyspnea, syncope, tachycardia.

Central Nervous System: nervousness, vertigo, depression, paresthesia.

Dermatologic: rash, pruritus, alopecia, lichen planus.

Genitourinary: urinary frequency, incontinence, impotence, priapism.

EENT: blurred vision, reddened sclera, epistaxis, tinnitus, dry mouth, nasal congestion.

Other: diaphoresis.

Single reports of pigmentary mottling and serous retinopathy, and a few reports of cataract development or disappearance have been reported. In these instances, the exact causal relationship has not been established because the baseline observations were frequently inadequate.

In more specific slit-lamp and funduscopic studies, which included adequate baseline examinations, no drug-related abnormal ophthalmological findings have been reported.

DOSAGE AND ADMINISTRATION: The dose of MINIPRESS (prazosin hydrochloride) should be adjusted according to the patient's individual blood pressure response. The following is a guide to its administration:

Initial Dose: 1 mg two or three times a day. (See Warnings.)

Maintenance Dose: Dosage may be slowly increased to a total daily dose of 20 mg given in divided doses. The therapeutic dosages most commonly employed have ranged from 6 mg to 15 mg daily given in divided doses. Doses higher than 20 mg usually do not increase efficacy; however, a few patients may benefit from further increases up to a daily dose of 40 mg given in divided doses. After initial titration some patients can be maintained adequately on a twice daily dosage regimen.

Use With Other Drugs: When adding a diuretic or other antihypertensive agent, the dose of MINIPRESS (prazosin hydrochloride) should be reduced to 1 mg or 2 mg three times a day and retitration then carried out.

HOW SUPPLIED: MINIPRESS (prazosin hydrochloride) is available in 1 mg (white #431), 2 mg (pink and white #437) capsules in bottles of 250, 1000, and unit dose institutional packages of 100 (10 x 10's); and 5 mg (blue and white #438) capsules in bottles of 250, 500 and unit dose institutional packages of 100 (10 x 10's).

More detailed information available on request.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Yorke Medical Books, Box C-757, Brooklyn, NY 11205 AJCG3

coronary artery, and this response was related to the extent of necrosis found in equivalent segments of corresponding pathologic slabs. Remote nonnecrotic segments always responded to nitroglycerin by significant augmentation of segmental LV function (systolic fractional area change and systolic wall thickening). Five hours after occlusion, segments with necrosis <40% exhibited a significant nitroglycerin-induced potentiation in segmental LV function, whereas segments with necrosis >60% showed no potentiation with nitroglycerin. Segments with eventual necrosis >80% had no significant potentiation as early as 30 minutes after occlusion. It is concluded that nitroglycerin-induced potentiation of segmental LV function is closely associated with the extent of segmental myocardial necrosis and that 2-D echocardiographic study of potentiation might be useful for characterizing viability of ischemic myocardium.

184 Nuclear Magnetic Resonance Imaging of Acute Myocardial Infarction in Dogs: Alterations in Magnetic Relaxation Times

CHARLES B. HIGGINS, ROBERT HERFKENS, MARTIN J. LIPTON, RICHARD SIEVERS, PHILIP SHELDON, LEON KAUFMAN, and LAWRENCE E. CROOKS

Nuclear magnetic resonance imaging was used to study 24-hour-old acute myocardial infarctions in 8 excised canine hearts. Spin echo nuclear magnetic resonance imaging in each instance demonstrated the area of infarction as a region of increased signal intensity compared that in normal myocardium. For each dog the T1 value was greater for the infarct region; however, the group mean value for T1 of the infarct region was not significantly greater than that for the normal region. The T2 value was discriminate for all dogs, and the mean value for the infarct region was significantly different from that for normal myocardium.

189 Effects of Coronary Occlusion on Flow in the Distribution of a Neighboring Stenotic Coronary Artery in the Dog

JEFFREY S. SCHWARTZ, JAY N. COHN, and ROBERT J. BACHE

The effect of left anterior descending (LAD) coronary occlusion on flow through a stenotic left circumflex artery (LC) was studied in open-chest dogs. In the presence of a severe LC stenosis, LAD occlusion caused an increase in LC stenosis resistance and a decrease in blood flow through the stenotic LC. Partial collapse of the LC stenosis due to a decrease in intraluminal pressure in the stenotic segment may have been responsible for this finding. In a second group of dogs the LC stenosis was adjusted so that anterograde flow through the LC did not change after LAD occlusion. However, subendocardial flow (measured with radioactive microspheres) to the area supplied by the stenotic LC decreased, possibly because of a decrease in coronary pressure distal to the stenosis and an increase in left ventricular diastolic pressure. A decrease in flow to myocardium supplied by a stenotic coronary artery may occur when a neighboring artery is occluded.

196 Roles of the Right Ventricular Free Wall and Ventricular Septum in Right Ventricular Performance and Influence of the Parietal Pericardium During Right Ventricular Failure in Dogs

MASATO TANI

The roles of the right ventricular (RV) free wall and ventricular septum in RV performance were studied in the canine heart with the pericardium intact. Acute ischemia of the RV free wall decreased the RV stroke work index more than that of the ventricular septum. The response of the RV stroke work index to volume loading was also decreased. Combined RV free wall and ventricular septal ischemia produced more severe and predominant RV dysfunction. After combined ischemia, pericardiotomy improved the RV stroke work index as well as the left ventricular stroke work index, although the increase in the former was greater than that in the latter. The results of this study suggest that (1) the RV free wall was a more important role than the VS in RV performance, (2) predominant RV failure can be induced experimentally, and (3) the pericardium has a restrictive effect on the damaged and dilated right ventricle.

203 Effect of Fluocarbon Exchange Transfusion on Myocardial Infarction Size in Dogs

GRAHAM R. NUNN, GARLAND DANCE, JENNIFER PETERS, and LAWRENCE H. COHN

Fluosol DA (20%), a perfluocarbon with high oxygen solubility, was administered by concurrent exchange transfusion (30 ml/kg) to anesthetized, open-chest, adult greyhounds (n = 9) 1 hour after left anterior descending coronary ligation. Mechanical ventilation using 100% oxygen was used throughout. A second similar group (n = 9) received 0.9% normal saline solution (30 ml/kg) and a third group (n = 9) received no further intervention. Systemic, right atrial and left atrial pressures were not altered by the exchange transfusion. Vital stain dye techniques were used to define areas at risk (A_R) (monastryl blue) and necrosis (A_N) (triphenyltetrazolium chloride). Fluosol DA significantly decreased the A_N/A_R ratio compared with values in the control and saline solution groups. Thus, fluocarbon exchange transfusion may reduce infarct size when administered after coronary occlusion.

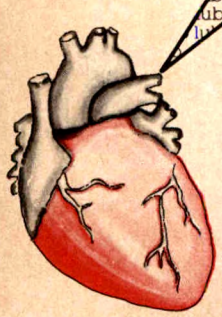
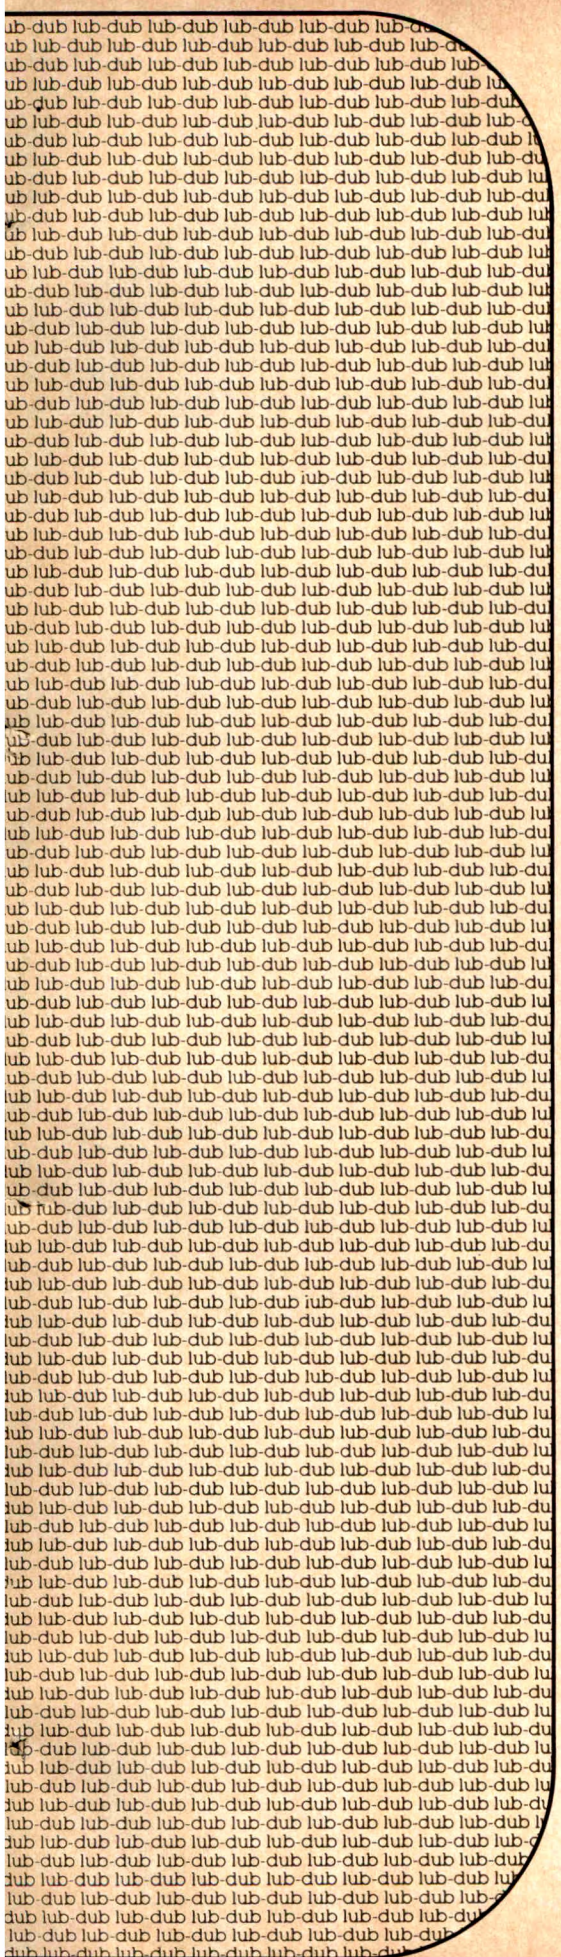
25,000,000,000 beats later...



and counting



Norpace®

(disopyramide phosphate)

100-mg and 150-mg capsules

The brand that counts most often in control of dysrhythmia

Five years on the market...7 million patient-months of experience...more than 7 million prescriptions dispensed...and the beat goes on.

Norpace® CR

(disopyramide phosphate)

controlled release
100-mg and 150-mg capsules

True 12-hour dosing convenience

Now, with Norpace CR, you can add true 12-hour dosing convenience to the established efficacy of Norpace...with no increase in cost to the patient.

As a consequence of the negative inotropic properties of disopyramide phosphate, adequate cardiac function must be established and maintained. Norpace/Norpace CR should not be used in patients with uncompensated or marginally compensated CHF or hypotension unless the condition is secondary to cardiac dysrhythmia.

The leading branded antiarrhythmic agent...Norpace

SEARLE

Please see the next page for a brief summary of the complete prescribing information.

Norpace®
disopyramide phosphate) 100-mg and 150-mg capsules

Norpace® CR controlled release
disopyramide phosphate) 100-mg and 150-mg capsules

he leading branded antiarrhythmic agent

efore prescribing, please consult current complete prescribing information, a summary of which llows: **Indications:** For suppression and prevention of recurrence of the following cardiac ar-ythmias: unifocal premature (ectopic) ventricular contractions; premature (ectopic) ventricular ntractions of multifocal origin; paired premature ventricular contractions (couplets); and isodes of ventricular tachycardia (persistent ventricular tachycardia is ordinarily treated with C. cardioversion). Norpace is equally effective in both digitalized and nondigitalized patients. It also equally effective in treating primary cardiac arrhythmias and those which occur in associ-ion with organic heart disease including coronary artery disease. Norpace CR should not be ed initially if rapid establishment of disopyramide plasma levels is desired. Oral disopyramide osphate has not been adequately studied in patients with acute myocardial infarction or with rsistent ventricular tachycardia or atrial arrhythmias and is not indicated for arrhythmias due digitalis intoxication. The value of antiarrhythmic drugs in preventing sudden death in patients th serious ventricular ectopic activity has not been established. **Contraindications:** Cardiogenic ock, preexisting second- or third-degree AV block (if no pacemaker is present), or known persensitivity to the drug. **Warnings: Norpace or Norpace CR may cause or worsen con-stive heart failure (CHF) or produce severe hypotension as a consequence of its negative otropic properties. Hypotension has been observed primarily with primary cardiomyopathy inadequately compensated CHF. Norpace or Norpace CR should not be used in patients th uncompensated or marginally compensated CHF or hypotension unless the condition is condary to cardiac arrhythmia. Patients with a history of heart failure may be treated th Norpace or Norpace CR, but careful attention must be given to maintaining cardiac nction, including optimal digitalization. If hypotension occurs or CHF worsens, Norpace or rpace CR should be discontinued and, if necessary, restarted at a lower dosage only ter adequate cardiac compensation has been established. Norpace or Norpace CR should discontinued if significant widening (greater than 25%) of the QRS complex occurs. Pro-ngation of the Q-T interval (corrected) and worsening of the arrhythmia may occur. Pa-nts who have evidenced prolongation of the Q-T interval in response to quinidine may be particular risk. If Q-T prolongation greater than 25% is observed and if ectopy continues, e patients should be monitored closely, and discontinuation of Norpace or Norpace CR nsidered. In rare instances significant hypoglycemia has been reported during Norpace erapy. The concomitant use of Norpace or Norpace CR with other Type 1 antiarrhythmic ents and/or propranolol should be reserved for patients with life-threatening arrhythmias o are demonstrably unresponsive to single agent antiarrhythmic therapy. Such use may oduce serious negative inotropic effects, or may excessively prolong conduction. Patients ceiving more than one antiarrhythmic drug must be carefully monitored. If first-degree rt block develops, the dosage of Norpace or Norpace CR should be reduced. If the ck persists, continuation of Norpace or Norpace CR must depend upon an assessment benefit versus risk. Development of second- or third-degree AV block or uni-, bi-, or ascicular block requires discontinuation of drug unless the ventricular rate is adequately ntrolled by a pacemaker. Because of its anticholinergic activity, disopyramide phosphate ould not be used in patients with glaucoma, myasthenia gravis or urinary retention, ess adequate overriding measures are taken. In patients with a family history of ucoma, intraocular pressure should be measured before initiating Norpace or Norpace therapy. Precautions:** Patients with atrial flutter or fibrillation should be digitalized prior to rpace or Norpace CR administration to ensure that drug-induced enhancement of AV conduc-does not allow a ventricular rate beyond physiologically acceptable limits. The effect of Nor-e or Norpace CR is presently uncertain in patients with sick sinus syndrome, Wolff-Parkinson-ite syndrome, or bundle branch block. Patients with myocarditis or other cardiomyopathy may elop significant hypotension in response to the usual dosage of disopyramide phosphate. erefore, a loading dose of Norpace should not be given to such patients, and initial dosage subsequent dosage adjustments should be made under close supervision. Norpace dosage uld be reduced in patients with impaired renal or hepatic function and the electrocardiogram efully monitored for signs for overdosage. Norpace CR is not recommended for patients with ere renal insufficiency. Concomitant administration of disopyramide phosphate with phenytoin ther hepatic enzyme inducers may cause lower disopyramide plasma levels. Antiarrhythmic gs may be ineffective in patients with hypokalemia, and their toxic effects may be enhanced atients with hyperkalemia. Therefore, potassium abnormalities should be corrected before rting Norpace or Norpace CR therapy. Safe use in pregnancy has not been established. Diso-amide has been found in human fetal blood. **Norpace has been reported to stimulate con-ctions of the pregnant uterus.** Use of Norpace or Norpace CR in pregnant women requires the potential benefit be weighed against possible hazards to the fetus. Following oral admin-ation, disopyramide has been found in human milk at a concentration not exceeding that in ma. If use of the drug is deemed essential, an alternate method of infant feeding should be ituted. Effects of Norpace or Norpace CR on the fetus during delivery or on the course of r and delivery are unknown. **Adverse Reactions:** Dry mouth, urinary hesitancy, constipation, red vision, dry nose/eyes/throat, urinary retention, urinary frequency and urgency, impotence, sea, pain/bloating/gas, anorexia, diarrhea, vomiting, nervousness, dizziness, general gue/muscle weakness, headache, malaise, aches/pains, hypotension, congestive heart failure, diac conduction disturbances, edema/weight gain, shortness of breath, syncope, chest pain, eralized rash/dermatoses, itching, hypokalemia, elevated cholesterol/triglycerides, depression, mnia, 'dysuria, numbness/tingling, elevated liver enzymes, AV block, elevated BUN, elevated atinine, decreased hemoglobin/hematocrit, and hypoglycemia. Acute psychosis, cholestatic ndice, and agranulocytosis, all three reversible, have been reported, as have fever, respiratory culty, thrombocytopenia, and gynecomastia. **Dosage and Administration:** Dosage must be in-dualized on the basis of response and tolerance. The usual adult dosage is 400 to 800 mg/day n in divided doses: q6h for Norpace and q12h for Norpace CR. **See current complete scribing information for dosage recommendations.**

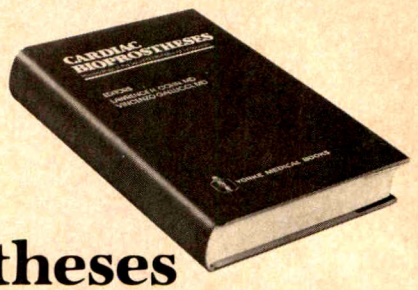
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982*.

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

CORONARY HEART DISEASE

Intracoronary Thrombus in Nontransmural Myocardial Infarction and in Unstable Angina Pectoris

JAY B. MANDELKORN, MD, NELSON M. WOLF, MD, SURENDER SINGH, MD, JAY A. SHECHTER, MD, ROBERT I. KERSH, MD, DAVID M. RODGERS, MD, MARK B. WORKMAN, MD, LAMBERTO G. BENTIVOGLIO, MD, STEVEN M. LaPORTE, MD, and STEVEN G. MEISTER, MD,
With the technical assistance of BARBARA TUCKER

Although intracoronary thrombus formation plays a major role in acute transmural myocardial infarction (MI), its occurrence in unstable angina (UA) and nontransmural MI has not clearly been established. To determine whether intracoronary thrombus does occur in these syndromes, coronary arteriography was performed before, during, and after intracoronary nitroglycerin and streptokinase infusion in 17 patients. None of the 8 patients with nontransmural MI and 1 of the 9 patients with UA responded to intracoronary nitroglycerin. Seven of 8 patients with nontransmural MI and 4 of 9 patients with UA responded to streptokinase infusion with opening of an occluded vessel, an increase in stenotic diameter, dissolution of an intracoronary filling defect, or a combination of these. Serial opening and closing of ischemia-related vessels occurred spontaneously and in response to streptokinase in some patients in whom thrombolysis was demonstrated. Evidence of thrombolysis was not seen in any patient studied longer than 1 week from the onset of the rest pain syndrome.

The finding of thrombolysis in several patients with nontransmural MI and UA suggests that intracoronary thrombus formation plays a pathogenetic role in some patients with these ischemic syndromes.

Recent necropsy[1–3] and angiographic studies[4–7] have established that intracoronary thrombus plays an important role in the genesis of acute transmural myocardial infarction (MI). However, evidence of thrombus involvement in the pathogenesis of nontransmural MI and unstable angina (UA) is less clear. Roberts and Buja[8] found no intracoronary thrombus at necropsy in 8 patients dying after nontransmural MI. Similarly, Erlich and Shinohara[9] found intracoronary thrombus in only 2 of 20 such patients at autopsy. Rentrop et al[6] found no angiographic evidence of clot lysis when 5 patients with UA were given intracoronary streptokinase. However, Vetrovec et al[10] and Holmes et al[11] both described intracoronary lucencies suggestive of intracoronary thrombi as an infrequent finding in some patients undergoing cardiac catheterization for UA or nontransmural MI. However, these intracoronary lucencies were not positively identified as thrombus in either study. To further clarify whether intracoronary thrombus does occur in these syndromes, we performed coronary arteriography before, during, and after in-

From the Medical College of Pennsylvania, Department of Medicine, Division of Cardiology, Philadelphia, Pennsylvania. Manuscript received November 1, 1982; revised manuscript received April 6, 1983, accepted April 6, 1983.

tracoronary streptokinase infusions in 17 patients with recent severe UA or nontransmural MI.

Methods

The patients in this study were drawn from the general population of patients referred for cardiac catheterization at our institution between March 1981 and February 1982. Group I consisted of 8 patients with nontransmural MI. These patients had either prolonged or frequently recurrent pain at rest. All had abnormal electrocardiograms, but none evolved pathologic Q waves. All patients had an increase in total creatine kinase to >150% of laboratory normal within 24 hours of their ischemic symptoms. Creatine kinase, myocardial band, was detected in all of these patients. Clinical features in Group I patients are summarized in Table I.

Group II consisted of 9 patients with severe UA or intermediate syndrome. The clinical and electrocardiographic profile was similar to that of the Group I patients. However, none of these patients had elevation of creatine kinase or its myocardial fraction. Clinical features of Group II patients are summarized in Table II.

Patients with bleeding diatheses, hemorrhagic peptic ulcer disease, recent cerebrovascular accident, recent surgical procedures, prior exposure to streptokinase, or age >70 years were excluded from the study. Only patients with a readily identifiable ischemia-related vessel were included in the study. We defined an ischemia-related artery as that occluded or stenosed vessel most closely corresponding to an electrocardiographically or ventriculographically determined area of ischemia, or an isolated coronary artery stenosis >70%. Only a small fraction of patients with UA and nontransmural MI fulfilled these criteria, gave informed consent, and were included in this study.

Left ventriculography and selective coronary arteriography using the Judkins technique were performed. After initial visualization of the coronary anatomy, a bolus of 200 μg of nitroglycerin was given directly into the ischemia-related vessel and angiography was repeated. Streptokinase was then infused directly into the ischemia-related artery at 4,000 units/min for the first 60 minutes and at 2,000 units/min for the next 30 minutes. Repeat coronary arteriograms were performed at 15 minutes intervals during streptokinase infusion in the projection best demonstrating the obstructing lesion. Creatine kinase and its myocardial fraction were obtained immediately before and after streptokinase infusion and at 6-hour intervals for 48 hours thereafter.

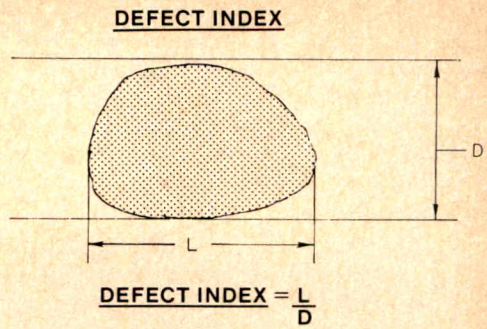

FIGURE 1. Scheme for determination of the defect index. D = any consistent adjacent diameter of the vessel; L = any consistent diameter of the filling defect.

All measurements of coronary anatomy were made by at least 2 independent observers from the screen of a model XR-35 Vanguard projector. A magnifying glass calibrated in 0.5 mm gradations was used. To determine the percentage of stenosis, the narrowest stenotic diameter was compared with the diameter of an uninvolved segment located immediately distal in the vessel. Measurements on single frames, in identical projections, were made before and after nitroglycerin, at the conclusion of streptokinase infusion, and at the time of the delayed study if this was performed.

A positive anatomic response to nitroglycerin or streptokinase was defined as conversion of an occluded vessel to a patent vessel, a change in stenosis diameter >20% in any consistent projection,[12] or dissolution of or a measurable decrease in the size of an intraluminal filling defect. To quantitate changes in the size of filling defects, we devised a defect index (Fig. 1). This index related any consistent diameter of the filling defect to the diameter of the vessel measured nearby in order to cancel out magnification effects. In a series of 20 separate measurements we found that interobserver variance in calculating this index did not exceed 20%. Accordingly, a 40% or greater reduction in the defect index was considered to be measurable and to represent thrombus lysis.

Ten patients (6 in group I and 4 in group II), responding to streptokinase, had repeat angiography 7 to 14 days after initial study. All were maintained on anticoagulation with intravenous heparin in the interim.

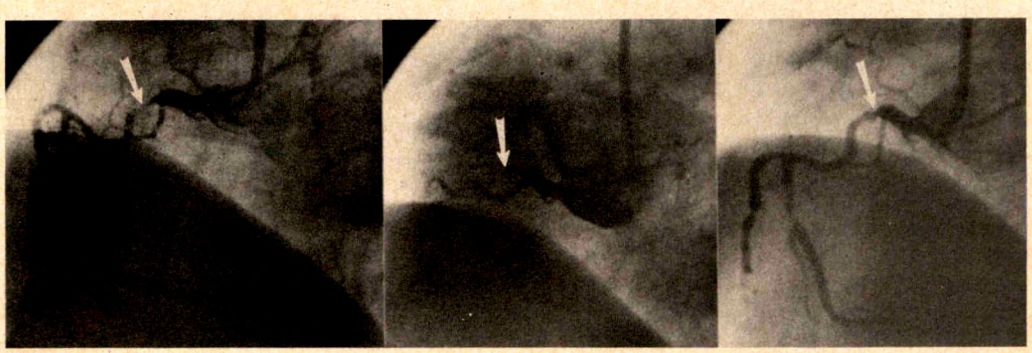

FIGURE 2. Right coronary artery in the left anterior oblique projection in patient RK with nontransmural myocardial infarction and recurrent chest pain episodes (see text). **Left panel,** the initial appearance of the right coronary artery. The **arrow** points to a translucent intraluminal filling defect giving the appearance of severe stenosis. **Middle panel,** the same vessel during an episode of chest pain. The vessel is occluded at the site of the filling defect (**arrow**). The vessel failed to reopen with intracoronary nitroglycerin. **Right panel,** the same vessel after streptokinase infusion. The vessel is now reopened and the stenosis has been markedly reduced. Nearly complete dissolution of the filling defect has occurred. The **arrow** points to the area where the filling defect was previously seen.

Results

Group I: nontransmural MI: Seven of 8 patients with nontransmural MI had anatomic changes in response to streptokinase infusion and were considered to have had lysis of intracoronary thrombi. No patient had any change in response to intracoronary nitroglycerin. All 7 responding patients had reduction of their filling defect indexes >40%. In 3 the defect was no longer visible at the conclusion of streptokinase infusion. Four patients also had a significant increase in luminal diameter at the site of stenosis. Two of these patients (EG and AC in Table I) had totally occluded ischemia-related vessels on initial angiography. In both, the vessels were unaffected by intracoronary nitroglycerin. Both partially reopened spontaneously and subsequently showed significant reduction or total elimination of the filling defect in response to streptokinase. Two other patients (RK and SC in Table I) had initially patent ischemia-related vessels which became totally occluded during the course of the study. Neither responded to intracoronary nitroglycerin but both reopened during streptokinase infusion and ultimately showed substantial improvement over their original anatomy at the end of the infusion (Fig. 2).

Six of the 7 patients in Group I initially responding to streptokinase were anticoagulated with intravenous heparin infusions sufficiently long to prolong partial thromboplastin 2 to 3 times normal and restudied within 2 weeks. In 3 patients who had residual filling defects, these were found to have undergone complete dissolution. One of these patients also showed subsequent improvement of stenotic diameter. Two other patients showed no change from their immediate poststudy status. One patient was restudied on an emergency basis because of total occlusion of the ischemia-related vessel, when heparin was discontinued in preparation for surgery (Fig. 3).

Group II: unstable angina: Four of 9 patients in this group had a positive anatomic response to streptokinase, 2 with an increase in stenotic diameter and 2 with complete dissolution of a filling defect. One of these (JM in Table II) initially reopened a totally occluded vessel in response to intracoronary nitroglycerin, leaving a major stenosis and an intraluminal defect that was then

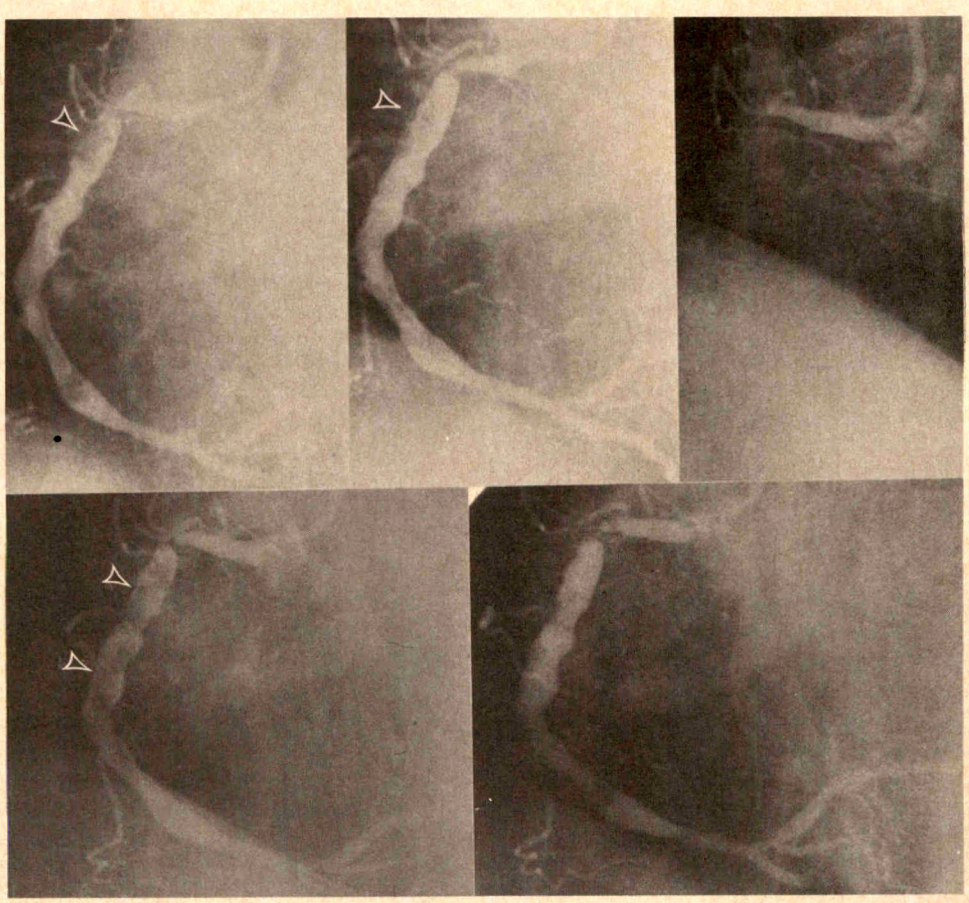

FIGURE 3. Right coronary artery in the left anterior oblique projection from patient JY with an acute nontransmural myocardial infarction (see text). **Top left panel,** the initial appearance of the right coronary artery. Severe proximal stenosis is associated with a large filling defect (**arrow**). **Top middle panel,** the vessel after streptokinase infusion. The stenosis is unchanged. The filling defect has decreased in size and is barely visible (**arrow**). **Top right panel,** a study performed 10 days after streptokinase infusion. Two hours after heparin was stopped, the patient had recurrent chest pain. The right coronary artery is occluded at the site of the previous stenosis. Intracoronary nitroglycerin failed to reopen the vessel. **Bottom left panel,** the vessel after reopening with intracoronary urokinase. Large filling defects are seen (**arrows**). Later in the infusion these defects embolized distally. **Bottom right panel,** taken after completion of urokinase infusion. The filling defects are no longer seen.

eliminated by streptokinase. Another patient (CL in Table II) initially reopened a totally occluded vessel in response to angiographic dye alone, leaving severe stenosis and an apparent filling defect. Intracoronary nitroglycerin produced no further change. Streptokinase infusion increased the vessel diameter at the stenotic site. An example of a patient from Group II is seen in Figure 4.

Two patients initially responding to streptokinase showed further anatomic change on restudy after 1 week of anticoagulation with heparin. One had a significant increase in luminal diameter. The other showed complete disappearance of a large intraluminal filling defect.

Although most patients were studied the day of the chest pain episode, we were unable to demonstrate thrombolysis in any patient in either group who was studied longer than 1 week after the onset of the rest pain syndrome.

Discussion

We found evidence of angiographic changes in the ischemia-related vessels when streptokinase was administered to 7 of 8 patients with nontransmural MI and 4 of 9 patients with UA. In all instances, the changes reported were visible to the unaided eye. Measurements were made to provide quantitative documentation. These findings establish the occurrence of intracoronary thrombus in some patients with these 2 syndromes. As such, they are in keeping with several earlier observations implicating thrombus formation in the pathogenesis of these syndromes. Folts et al[13] demonstrated spontaneous intermittent occlusions of partially obstructed canine coronary arteries by platelet thrombi. Hirsh et al[14] showed increased transmyocardial thromboxane B_2 ratios in patients with UA, whereas Sobel et al[15] demonstrated increased circulating levels of platelet specific factors (beta thromboglobulin and platelet factor IV) shortly after episodes in man. Neill et al[16] observed a high incidence of total occlusion of previously patent ischemia-related vessels in patients restudied 4 months after episodes of UA. Interestingly, Lawrence et al[17] performed a small prospective controlled study of intravenous fibrinolytic therapy in patients with unstable angina pectoris. In a 6-month follow-up, they found significantly fewer cardiovascular events in the streptokinase-treated patients than in the controls. Vetrovec et al[18] administered streptokinase to 7 patients with unstable ischemic syndromes related to obstructions in the native coronary vessels. Minor angiographic changes were noted in 4 and major changes only in 1 patient. Because in that individual a guide wire was employed to reopen the vessel, thrombolysis was not clearly established.

The absence of evidence for intracoronary thrombus in 5 of 9 of our patients with UA and 1 of 8 patients with nontransmural MI suggests that other processes such as coronary spasm may have been involved. In this connection, Parodi et al,[19] using scintigraphic techniques, demonstrated episodic reduction in regional myocardial perfusion in patients with UA during rest pain. These investigators attributed this finding to intermittent coronary artery spasm. Moreover, Maseri et al[20] observed coronary spasm angiographically in some "preinfarctional" patients.

Alternatively, our methods may not have been sufficiently sensitive to detect intracoronary thrombus in all patients in whom it may have occurred. In experimental preparations of Folt et al[13] intracoronary thrombi formed, disappeared, and reformed respectively over a period of minutes of hours, causing intermittent vessel obstruction in the process. It is conceivable that a similar process occurs during UA in man and that intracoronary thrombi are not always present or sufficiently large and distinct enough to be visualized at the time of angiography. We did not document intracoronary thrombus in any patient who was studied longer than 1 week after the onset of unstable symp-

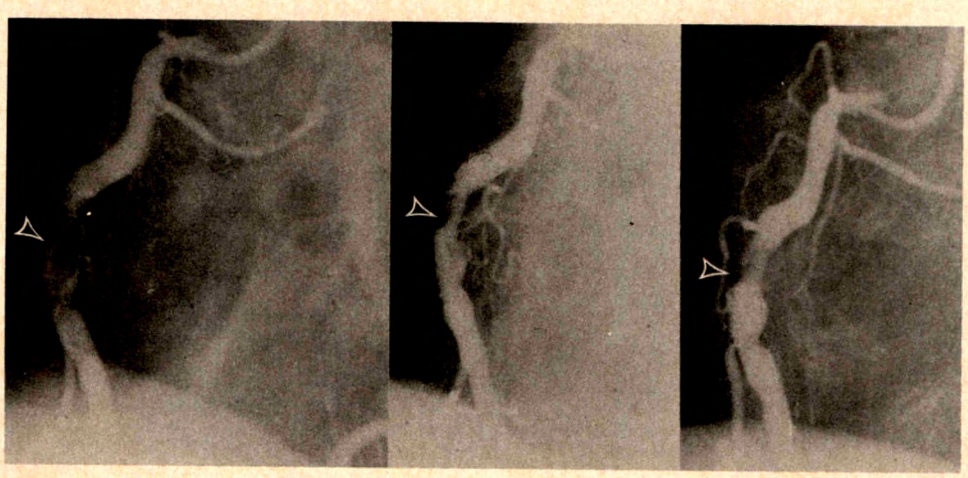

FIGURE 4. Right coronary artery in the left anterior oblique projection from patient JH with unstable angina (see text). **Left panel,** the initial appearance of the right coronary artery. There is a severe stenosis of the proximal vessel associated with a globular intraluminal filling defect (**arrow**). **Middle panel,** taken immediately after streptokinase infusion. The stenosis (**arrow**) was reduced significantly, but the filling defect has not been measurably decreased. **Right panel,** after 6 days of heparin therapy. The severity of the stenosis is unchanged (**arrow**) and the filling defect is no longer present.

toms. Moreover, intracoronary thrombi that may have been present for some time became organized and no longer subject to lysis by streptokinase.

Our experience does suggest an alternative mechanism for episodic reduction in regional myocardial perfusion, namely, intermittent obstruction of a coronary artery by thrombus superimposed on preexisting atherosclerotic obstructive lesions. We observed this process angiographically at various stages in one of our patients with unstable angina (CL) and in 4 patients with nontransmural myocardial infarction (RK, JY, SC, AC).

These observations also suggest a possible common cause of severe unstable angina pectoris: nontransmural and transmural myocardial infarction. Intracoronary thrombus formation may be a common factor in all 3. The specific clinical syndrome that results may be a function of the duration of total obstruction as well as the size and extent of the coronary artery or branch involved and the availability of collateral circulation. It must be emphasized that the patients included in this study represented only a fraction of the patients with unstable angina or nontransmural myocardial infarction seen in our institution during the study. Thus, no inferences regarding the true incidence of intracoronary thrombus in these conditions can be drawn. Obviously, further study is needed to delineate the incidence and importance of intracoronary thrombus in these ischemic syndromes as well as to critically explore the possible therapeutic potential of pharmacologic agents capable of lysing or preventing intracoronary thrombi.

Acknowledgment: We are particularly grateful to Drs. Michael Goodkin, Robert Krause, Louis Leo, John O'Hara, Rick Okagawa, John Urbach, and Joseph Uricchio for permitting us to study their patients. We are also exceedingly grateful to Susan Dietsch, RN, and the personnel of the catheterization laboratory for their unstinting aid in these particularly difficult studies done at all hours of the day or night. We would like to thank Irma Barr for her help and patience in preparing this manuscript.

Comparison of High-Dose and Medium-Dose Propranolol in The Relief of Exercise-Induced Myocardial Ischemia

KENNETH G. MORRIS, MD, MICHAEL B. HIGGINBOTHAM, MB, R. EDWARD COLEMAN, MD, DAVID G. SHAND, MB, PhD, and FREDERICK R. COBB, MD

The effects of medium-dose (160 mg/day) and high-dose (480 mg/day) oral propranolol were compared in 22 patients who had typical angina pectoris and objective evidence of myocardial ischemia during exercise. Left ventricular (LV) ejection fraction (EF) and wall motion score (WMS) (an index of regional LV dysfunction) were assessed by radionuclide angiography both at rest and during exercise to the pretreatment maximum work load. Functional class improved in 11 of the 22 patients during medium-dose propranolol therapy. Medium-dose propranolol reduced mean resting heart rate from 71 to 55 beats/min, exercise heart rate from 122 to 93 beats/min, and exercise systolic blood pressure from 183 to 162 mm Hg ($p < 0.001$ for each). The incidences of exercise-induced chest pain and S-T segment depression were reduced from 19 to 9 patients ($p < 0.001$), and from 20 to 10 patients ($p = 0.002$), respectively. Medium-dose propranolol had no effect on mean EF or WMS at rest, but improved function in ischemic regions during exercise; WMS decreased ($p = 0.001$), and mean exercise EF increased from 0.51 to 0.56 ($p = 0.025$). Compared with the medium dose, high-dose propranolol improved functional class in 3 additional patients, and further reduced mean resting heart rate (from 55 to 52 beats/min, $p = 0.001$) and mean exercise heart rate (from 93 to 86 beats/min, $p = 0.001$). Exercise-induced chest pain and S-T segment depression were abolished in a further 7 and 6 patients, respectively. Exercise EF and WMS improved further in several patients, but the changes were not statistically significant for the group ($p = 0.095$ and 0.082, respectively).

Thus, in patients with coronary artery disease and exercise-induced ischemia, propranolol reduced heart rate and blood pressure and the incidence of exercise-induced chest pain, electrocardiographic changes, and ischemic LV dysfunction. Although most of these effects were seen with medium-dose propranolol, higher doses provided additional relief of chest pain and S-T segment depression, and further improved global and regional LV function in several patients.

Propranolol, a nonselective beta-adrenergic antagonist, has been used for many years in the management of patients with ischemic heart disease. Several studies have shown that propranolol decreases the heart rate and blood pressure responses to exercise, and is effective in reducing the frequency of anginal attacks.[1–5]

Although it has been established that near-maximal beta-blockade is achieved with moderate doses of propranolol,[6] studies examining the effects of high doses of propranolol on symptoms, exercise tolerance, and left ventricular (LV) function in patients with ischemic heart disease have not yielded consistent results. Certain investigators have observed greater improvement in symptoms with high-dose than with medium-dose propranolol,[3,4] while others have noted that high-dose propranolol not only provided little additional benefit but also significantly impaired LV function.[7,8]

Several groups of investigators have reported recently[9,11] that propranolol in fixed daily doses ranging from 80 to 320 mg improved global and regional LV function during exercise in patients with coronary artery disease and exercise-induced myocardial ischemia; the relative effects of different doses were not compared in

these studies. The purpose of the present study was to compare the effects of medium-dose (160 mg/day) and high-dose (480 mg/day) propranolol on clinical symptoms and LV function in patients with typical angina pectoris and exercise-induced myocardial ischemia. Radionuclide measurements of global and regional LV function were compared at rest and at identical exercise work loads before and during treatment with medium-dose and high-dose propranolol. Plasma propranolol levels were measured to ensure drug compliance and to examine the relationship between plasma levels and measured effects of the drug.

Methods

Patient population: Twenty-two men aged 48 to 64 years participated in the study. All had typical angina pectoris, and had had angina and ≥1 mm horizontal or downsloping S-T segment depression during routine treadmill testing. Patients were required to have failure of the ejection fraction (EF) to increase by 0.05 and the appearance of a new wall motion abnormality during exercise radionuclide angiography.

Cardiac catheterization was performed for routine clinical indications in 12 patients. Significant coronary artery disease (defined by a ≥75% diameter stenosis of ≥1 major artery) was confirmed in each case; 5 patients had 2-vessel disease and 7 patients had 3-vessel disease. Myocardial infarction had been documented at least 3 months previously in 4 of the 12 patients who had undergone cardiac catheterization and in 7 of the 10 patients who had not. Ten patients were taking propranolol (40 to 160 mg/day) before entry into the study; the response to this therapy did not influence selection. No patient had symptoms of congestive heart failure.

Study protocol: Since this study concerned comparison of the effects of medium-dose and high-dose propranolol on objective indexes of LV function at equal work loads, an open protocol was used. The study involved 3 evaluations. Patients were first evaluated before commencement of the study drug; previously administered propranolol was discontinued for at least 2 weeks. The second evaluation followed 2 weeks of continuous therapy with 160 mg/day of propranolol. The dose was then increased to 480 mg/day and a third evaluation was performed 2 weeks later. In each case propranolol was given in 4 divided doses each day.

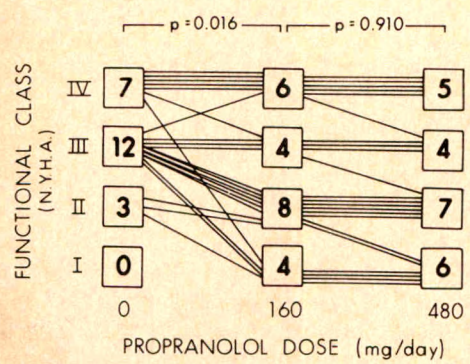

FIGURE 1. Clinical status, expressed as New York Heart Association (NYHA) functional class, of 22 patients with ischemic heart disease assessed before treatment with propranolol (0 mg/day) and subsequently during medium-dose (160 mg/day) and high-dose (480 mg/day) therapy. The number of patients in each functional class are shown for each of the 3 assessments. Probability (p) values were derived from chi-square analysis.

At each evaluation, a cardiovascular history was taken, a physical examination was performed, and a New York Heart Association functional class was assigned. Radionuclide angiography was performed at rest and during exercise.

Exercise radionuclide angiography: Each exercise test was performed with the patient in the postabsorptive state. All nitrates were withheld for at least 6 hours. For evaluations on the 2 doses of propranolol, tests were performed 2 to 3 hours after the previous dose; studies were scheduled for each patient at a similar time during the day. Patients exercised in the upright position on an isokinetic bicycle ergometer (Fitron, Lumex). The electrocardiogram was monitored continuously, and the standard limb leads and leads V_5 and V_6 were recorded initially and after each minute of exercise. Arterial blood pressure was measured by cuff manometry at rest and during each minute of exercise. Exercise began at 150 kpm/min (50 W); the work load was increased by 150 kpm every 3 minutes, at a constant pedalling rate of 60 rpm. For the pretreatment evaluation, exercise was continued until limited by moderate angina, ≥1 mm S-T segment depression, or severe fatigue. Each subsequent study was performed to the maximum level of work load achieved in the initial evaluation. To assess the effects of high-dose propranolol on exercise performance, patients were then encouraged to exercise further if they had not achieved 1 of the endpoints described above.

Multigated radionuclide angiograms were recorded by labelling red blood cells in vivo with 30 mCi of technetium-99m. Radionuclide angiograms were acquired using a Searle L.E.M. mobile scintillation camera with a high-sensitivity slant hole collimator, and an R-wave triggered gate interfaced to a Medical Data Systems A^2 computer. Studies were acquired in a histogram mode, in a 64 × 64 matrix of 24 frames each containing 125,000 counts. Acquisition time was approximately 1.5 to 2 minutes for each study; radionuclide angiograms were recorded before exercise and during the second and third minutes of the final exercise stage. Left ventricular EF was calculated using a varying region of interest technique. Regions were assigned by an operator-assisted semi-automated edge-detection program using standard software. Analysis of counts in each region allowed the construction of time-activity curves. Background-corrected end-diastolic (ED) and end-systolic (ES) counts were determined from the peak and trough of the time-activity curve respectively, and EF was calculated from the formula: EF = (ED counts − ES counts)/ED counts. LV wall motion was evaluated from an endless loop display of data from all 24 frames of the radionuclide angiogram. Wall motion was assessed by at least 2 blinded observers who arrived at a reading by consensus. The left ventriculogram in the left anterior oblique view was divided into 6 segments (2 septal, 2 inferoapical, and 2 posterolateral). A semiquantitative wall motion score (WMS) was calculated based on a score for each segment of normal = 0, hypokinetic = 1, akinetic = 2, and dyskinetic = 3.

Reproducibility of measurements: The reproducibility of the radionuclide measurements at rest and during maximal exercise was assessed in 9 men who had all criteria for the present study. Each patient underwent exercise radionuclide angiography on 2 occasions 1 to 2 weeks apart, without propranolol therapy. Initial exercise was performed to the endpoints previously described, and the second study was performed to an identical work load. The reproducibility of exercise-induced chest pain and S-T segment depression was also noted.

Serum propranolol levels: Blood samples were drawn 2 to 3 hours after propranolol administration. The plasma was removed after centrifugation and immediately refrigerated for subsequent measurement of propranolol levels. Serum

TABLE I Exercise Responses During Medium-Dose (P 160 mg) and High-Dose (P 480 mg) Propranolol Therapy

	Chest Pain			S-T Depression		
	+	−		+	−	
Pre	19	3	p = 0.002	20	2	p = 0.002
P 160 mg	9	13		10	12	
			p = 0.014			p = 0.049
P 480 mg	2	20		4	18	

Pre = pretreatment.

propranolol levels were measured by high-pressure liquid chromatography, using a modification of the technique described by Nation et al.[12]

Analysis: Functional improvement during therapy with medium-dose and high-dose propranolol therapy was assessed by chi-square analysis of the distribution of New York Heart Association functional class. Chi-square analysis was used also to compare the incidence of chest pain and S-T segment depression during exercise tests.

The nonparametric Wilcoxon signed-rank test for paired observations was used to assess differences (1) between pretreatment and medium-dose propranolol, and (2) between medium-dose and high-dose propranolol. Since assessment of more than 1 set of paired observations increases the chance of a "false significant" finding by approximately the number of sets tested,[13] a p value <0.03 was selected to indicate a significant change.

Results

Clinical responses: Clinical responses to different doses of propranolol are shown in Figure 1. Of the 22 patients studied, 11 improved by at least 1 functional class during therapy with medium-dose (160 mg/day) propranolol; however, 1 patient deteriorated from functional class III to functional class IV. During therapy with high-dose propranolol (480 mg/day), the patient who deteriorated to class IV during medium-dose therapy improved to class III; 2 patients who had not initially responded and 1 who had improved with medium-dose therapy improved by 1 functional class with the higher dose. Analysis of the group response showed significant overall improvement with medium-dose propranolol (p = 0.016) but no further change with high-dose therapy.

Exercise endpoints: Each of the 9 subjects who performed duplicate exercise tests without taking propranolol achieved the same maximum work load during each study. Chest pain and S-T segment depression during exercise were highly reproducible: 7 of 9 had chest pain and 7 of 9 had S-T segment depression on both occasions. In only 1 patient did either endpoint differ; 1 patient had S-T depression in the second study, but not in the first.

During the pretreatment bicycle exercise test in the propranolol study group, 19 of the 22 patients had chest pain and 20 had S-T segment depression (Table I). Compared with the pretreatment study, medium-dose propranolol significantly decreased each parameter; 9

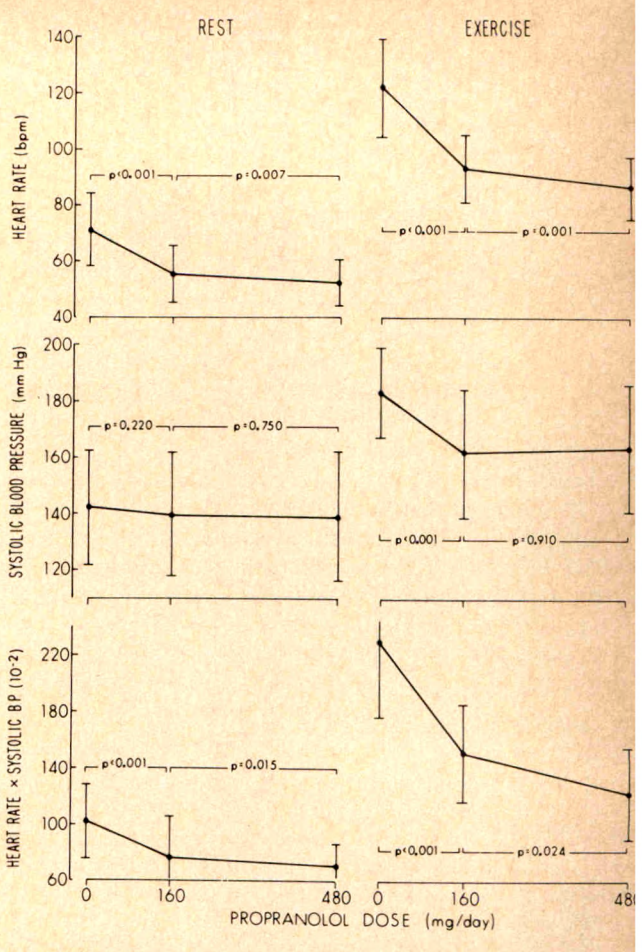

FIGURE 2. Effect of medium-dose (160 mg/day) and high-dose (480 mg/day) propranolol on heart rate (**upper panels**), systolic blood pressure (**middle panels**), and rate-pressure product. Exercise variables during propranolol therapy were measured at the pretreatment maximum work load. Data are shown as mean ± standard deviation. p values were derived from Wilcoxon signed rank tests (significant difference: p <0.03).

patients had chest pain (p = 0.002) and 10 had S-T segment depression (p = 0.002). High-dose propranolo showed a trend toward further improvement compared with the medium dose; 2 patients had chest pain (p = 0.014) and 4 had S-T segment depression (p = 0.049). Neither endpoint was present in 9 patients during medium-dose propranolol therapy and 18 patients during high-dose therapy. In these patients, exercise was limited by fatigue.

Propranolol had little effect on the maximum work load achieved during exercise testing. Three patients achieved an additional 150 kpm/min exercise work load with medium-dose propranolol, and another 7 patients were able to achieve a small additional increment of 100 kpm/min. With high-dose propranolol, only 2 patients increased their work load by 100 kpm/min compared with the medium dose. Exercise performance did not decrease in any patient.

Hemodynamic responses: In the 9 patients who exercised to a symptom-limited maximum on 2 occasions 1 to 2 weeks apart without receiving propranolol,

heart rate varied by 11 ± 8 beats/min at rest and by 8 ± 7 beats/min during exercise. Corresponding variations in systolic blood pressure were 11 ± 9 mm Hg and 8 ± 8 mm Hg, respectively.

The effects of medium-dose and high-dose propranolol on rest and exercise hemodynamic features are summarized in Figure 2. Medium-dose therapy effected a decrease in mean heart rate compared with pretreatment values from 71 to 55 beats/min (23%) at rest and from 122 to 93 beats/min (26%) during exercise ($p < 0.001$). Systolic blood pressure was not significantly affected at rest (mean 139 mm Hg compared with 142 mm Hg before treatment), but decreased slightly during exercise from 183 to 162 mm Hg ($p < 0.001$). High-dose as compared with medium-dose propranolol resulted in a small but significant additional decrease in heart rate. Resting heart rate decreased by 5% from 55 to 52 beats/min ($p = 0.001$) and exercise heart rate decreased by 7% from 93 to 86 beats/min ($p = 0.001$). Resting and exercise systolic blood pressure did not change further with high-dose therapy.

Coincident with the changes in heart rate and systolic blood pressure, medium-dose propranolol therapy decreased mean rate-pressure product by 25% from 102,000 to 76,000 at rest ($p < 0.001$) and by 34% from 229,000 to 151,000 during exercise ($p < 0.001$). High-dose propranolol caused a further small decrease in rate-pressure product, by 7% from 76,000 to 71,000 at rest ($p = 0.015$) and by 6% from 151,000 to 142,000 during exercise ($p = 0.024$).

Left ventricular function: Duplicate rest and exercise radionuclide studies performed in 9 patients demonstrated a high degree of reproducibility for estimates of EF and WMS. Differences between rest measurements were 0.021 ± 0.02 (standard deviation [SD]) for EF and 1.3 ± 1.0 for WMS; exercise values differed by 0.043 ± 0.044 for EF and 1.5 ± 1.1 for WMS.

Changes in rest and exercise EF during medium-dose and high-dose propranolol therapy are shown in Figure 3. Resting EF for the group did not change during treatment with either dose of propranolol; the mean value was 0.57 at each evaluation. Medium-dose propranolol resulted in a significant increase in exercise EF from 0.51 to 0.56 ($p = 0.025$); exercise EF increased by ≥0.08 (2 SD of the mean variability of the measurement) in 8 patients. No further increase in mean exercise EF resulted from the higher dose ($p = 0.095$); however, an absolute increase in exercise EF was seen in 16 patients compared with a decrease in only 5 patients, and exercise EF increased by ≥0.08 in an additional 3 patients compared with the medium-dose propranolol.

The change in EF during propranolol therapy was highly variable between patients. Figure 3 shows that subjects who had lower exercise EFs before therapy tended to have the greatest increases in exercise EF

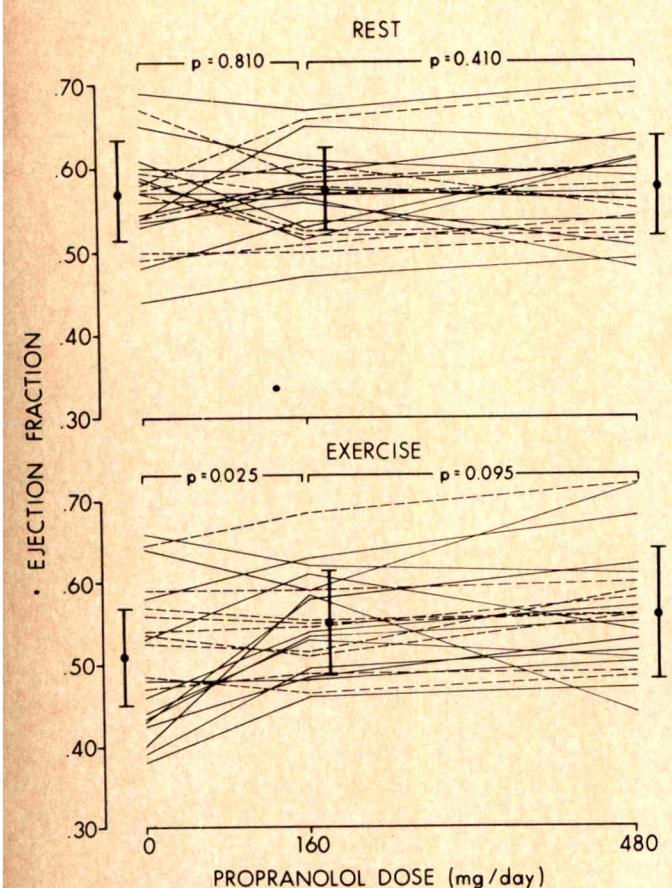

FIGURE 3. Changes in rest and exercise ejection fraction during medium-dose (160 mg/day) and high-dose (480 mg/day) propranolol therapy. Individual data are displayed for patients whose functional class improved (responders, **solid lines**) and for those in whom functional class did not improve (nonresponders, **broken lines**). **Bars** represent mean ± standard deviation. Analysis as in Figure 2.

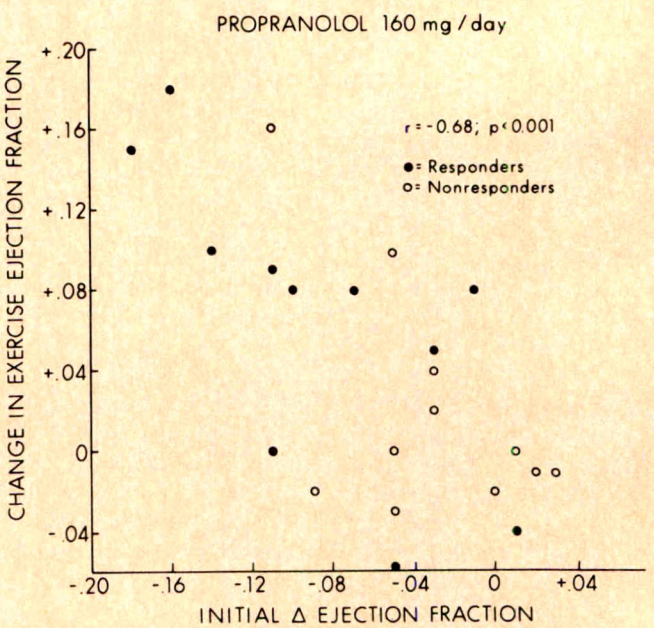

FIGURE 4. Relationship between pretreatment ejection fraction response to exercise (initial Δ ejection fraction) and change in exercise ejection fraction during medium-dose propranolol therapy. A marked initial decrease in ejection fraction was a significant univariate predictor of improvement in exercise ejection fraction with propranolol and of clinical response to therapy.

during therapy; of 11 patients whose pretreatment exercise EF was <0.05, the exercise EF increased in 9 during medium-dose propranolol therapy. Figure 4 illustrates the relationship between the pretreatment EF response to exercise and the change in exercise EF during medium-dose propranolol therapy, with $r = -0.68$, $p < 0.001$.

The relation between clinical response to medium-dose propranolol and the response of exercise-induced LV dysfunction is shown in Figures 3 and 4. Patients who improved by at least 1 functional class during the 2-week treatment period (solid lines in Figure 3, closed circles in Figure 4) demonstrated a greater decrease in EF during exercise before treatment, and a greater increase in EF during medium-dose propranolol than did patients who did not improve ($p < 0.03$, unpaired t test). Thus, 9 of 11 patients with exercise EFs <0.50 improved by 1 functional class; in 6 of these 9 patients exercise EF increased by ≥0.08.

Changes in EF between medium-dose and high-dose propranolol were small compared with the initial response to medium-dose therapy, and they were also variable. Two patients whose exercise EFs increased with medium-dose treatment demonstrated a decrease to the pretreatment level (by 0.07 and 0.14) with high-dose propranolol (Fig. 3). These changes were not accompanied by reversal of the improved wall motion seen in medium-dose therapy, suggesting a decrease in contractility in the normal or nonischemic segment.

Resting WMS did not change at either dose level of propranolol (Fig. 5). During exercise, WMS improved significantly during medium-dose propranolol therapy from 5.4 to 3.3 ($p = 0.001$); exercise WMS decreased by at least 2 (2 SD of the mean variability of the measurement) in 13 patients. The small difference in exercise WMS between medium-dose and high-dose therapy was not statistically significant for the group, but showed a trend toward further improvement ($p = 0.082$). This was supported by an absolute decrease in WMS in 9 patients compared with an increase in only 2 patients, and a decrease in WMS by ≥2 in an additional 2 patients.

Plasma propranolol levels: Plasma propranolol levels were obtained in all patients during medium-dose therapy and in 18 of 22 during high-dose therapy. A wide range of plasma propranolol levels was produced at each dose level of the drug; plasma propranolol ranged from 10 to 125 ng/ml during medium-dose therapy and from 61 to 525 ng/ml during high-dose therapy. In all except 1 patient who had plasma propranolol estimates at both dose levels, the value was higher with high-dose therapy than with medium-dose therapy. The 2 patients whose exercise EFs decreased to pretreatment values at the higher dose had serum levels of 83 and 267 ng/ml.

In an attempt to relate plasma propranolol levels to the extent of beta-blockade, the relationship between plasma propranolol and the percent reduction in exercise heart rate was examined (Fig. 6). Consistent with the findings of other investigators,[3,4,6] the relationship

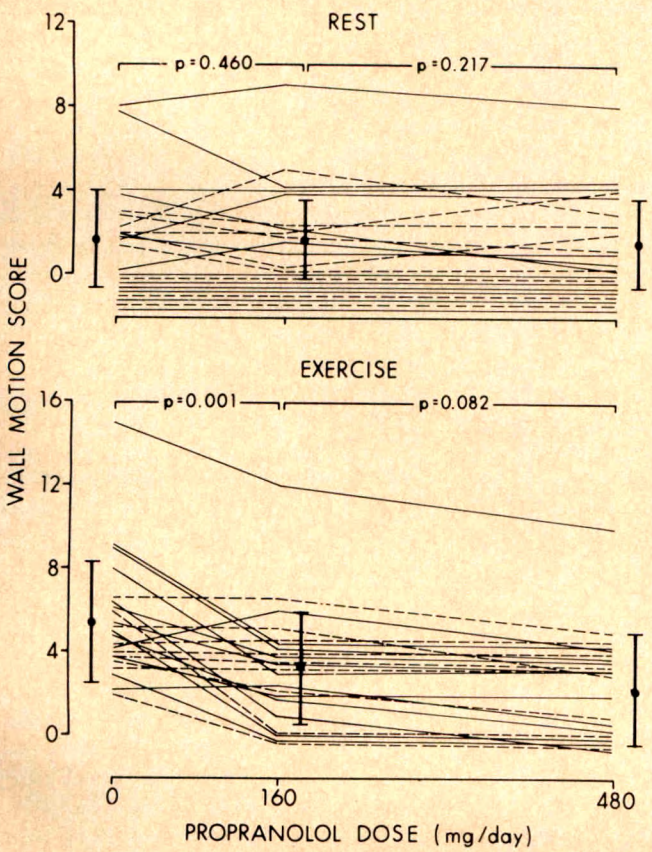

FIGURE 5. Changes in rest and exercise wall motion score during medium-dose and high-dose propranolol therapy. Data are represented as in Figure 3.

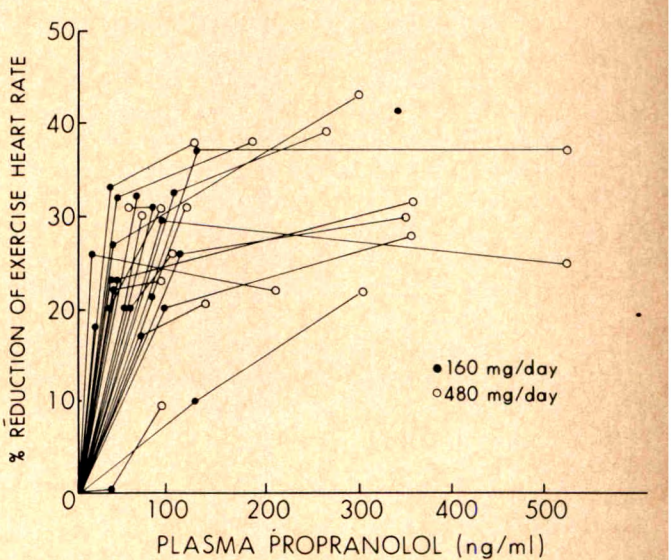

FIGURE 6. Relationship between plasma propranolol level and the degree of beta-adrenergic blockade as assessed by percent reduction of exercise heart rate. Medium-dose propranolol (160 mg/day, **closed circles**) produced plasma levels ranging from 10 to 125 mg/ml, and reduced exercise heart rate by approximately 25%. High-dose propranolol (480 mg/day, **open circles**) achieved plasma levels >200 mg/ml in many patients but had only a small additional beta-blocking effect.

between plasma propranolol and the percent reduction in exercise heart rate appeared exponential. Medium-dose propranolol produced substantial beta-blockade, consistent with the observed effects described earlier and represented in Figure 2. Linear regression analysis of the relationship between log plasma propranolol level and percent reduction in exercise heart rate at the 2 dose levels revealed a weak but significant relationship ($r = 0.36$, $p = 0.03$). Changes in exercise EF and WMS were not significantly related to log plasma propranolol ($r = 0.20$ and -0.19, respectively).

Discussion

These data demonstrate that most of the effects of propranolol on hemodynamic determinants of myocardial oxygen demand such as heart rate, blood pressure, and rate-pressure product, and on functional indexes of LV ischemia such as global EF and regional wall motion, are seen with a moderate dose. Although high-dose propranolol produced only a slight additional effect on these measured parameters, there was a significant further reduction in exercise chest pain and S-T segment depression; several patients further improved their functional class, and no patient experienced a deterioration of LV function with the high dose.

The beneficial effect of high-dose propranolol on anginal symptoms appears to support earlier observations by Prichard,[3] and Alderman,[4] and their co-workers that improvement in the control of exertional angina was progressive as dosage increased to levels equivalent to the higher dose used in our study. However, the changes in heart rate and blood pressure observed in the present study indicate that only minor additional beta-blockade resulted from the higher dose. The apparent discrepancy between clinical symptoms and hemodynamic effects may be explained by the patterns of physical activity that produce angina in patients with ischemic heart disease. In chronic stable angina, patients establish a habitual level of activity that corresponds to their pain threshold. Unless a conscious attempt is made to markedly increase that activity level, a small change in the threshold of angina may dramatically reduce the number of anginal attacks. Indeed, increases in objective measurements of exercise capacity in the studies cited above and in the present study were much smaller than the clinical improvement with high-dose therapy would suggest.

A further apparent inconsistency that requires consideration is that high-dose as compared with medium-dose propranolol significantly reduced chest pain and S-T segment depression, but effects on exercise-induced LV dysfunction were not significant for the group. First, it should be noted that there was not a major qualitative difference between these observations; changes in LV function were nearly significant for the group, and LV function did improve in the majority of patients with the higher dose. It is unlikely that functional changes were intrinsically less sensitive to ischemia than chest pain or electrocardiographic changes. Upton et al[14] observed that LV dysfunction often appeared before the onset of chest pain and S-T segment depression. The most likely explanation for the apparently inconsistent finding is the method used to record variables during the exercise test. Chest pain and S-T depression were used to determine endpoints of exercise and were recorded as binary variables; thus, small decreases in ischemia may result in highly significant decreases in the incidence of these parameters. In contrast, EF and WMS were not used as exercise endpoints and were quantitated as continuous variables; it follows that statistical analysis would be relatively insensitive to small changes in these measurements.

Changes in global EF must be interpreted in the light of differential effects of propranolol in normal and ischemic myocardium. Previous studies have demonstrated that propranolol in normal, young healthy subjects decreases exercise EF.[15] Theroux et al[16] observed in conscious dog preparations that propranolol improved wall contraction in ischemic regions, but decreased contraction in normal or nonischemic myocardium. Thus, in the presence of exercise-induced ischemia in man, propranolol may be expected to reduce contraction of nonischemic regions and increase contraction in ischemic regions. The effects on global EF will represent the net of these differing effects. An increase in EF during exercise after propranolol is likely to be due to improved function in the ischemic region; on the other hand, an unchanged exercise EF may result from improved function in an ischemic region which is cancelled by reduced function in the nonischemic areas. In the present study, the patients with the lowest exercise EFs and presumably the greatest amount of exercise-induced ischemia had the greatest increases in global EF during propranolol therapy. Two of 3 patients with exercise EF >0.60 actually decreased exercise EF with moderate-dose propranolol; these patients did not have a corresponding increase in WMS, indicating that the decrease in EF was due to an effect on nonischemic myocardium. The effects of propranolol on WMS were more consistent; in all but 1 patient, WMS either decreased or remained unchanged with moderate-dose propranolol. Consistent with the EF changes, subjects with higher exercise WMS tended to have the greatest decreases with propranolol.

In selecting an appropriate regimen of drug therapy, the benefits derived from increased dosage must be balanced against the potential disadvantages. In the case of propranolol, caution has been advised in the use of large doses because of possible depression of LV function. Epstein et al[17] have emphasized that the sympathetic nervous system plays an important part in the contractile response of the left ventricle to exercise, and it is possible that this is especially important in patients who have comprised LV function. The view that beta-adrenergic blockade may cause depression of LV function has been supported by the studies of Frishman,[7] Helfant,[18] Coltart,[19] and their co-workers, which demonstrated a decrease in various indexes of resting LV contractility in many patients after administration of increasing doses of propranolol. Despite these observations, data from the present study demonstrated no overall decrease in the LVEF with either medium-dose or high-dose propranolol; in fact, exercise LV function as determined by EF increased slightly in

most patients even with high-dose propranolol. These results support our own clinical impression that high-dose propranolol does not induce heart failure in patients with angina and normal or near-normal LV function at rest. However, they should not be extrapolated to patients who have LV dysfunction, since only 4 of our 22 subjects had a resting EF <0.50, and no subject had symptoms of heart failure.

A weak relation was seen in the present study between plasma levels of propranolol and exercise heart rate ($r = 0.36$), exercise EF ($r = 0.20$), and exercise WMS ($r = -0.19$). This is at least partially explained by the known dose-response relationship of the drug. As demonstrated by Coltart and Shand,[6] near maximal beta-blockade is produced by small doses of propranolol with correspondingly low plasma levels; both medium-dose and high-dose propranolol as used in the present study produce blood levels that lie on the plateau of the dose-response curve. The relationship between plasma levels and drug effect may be further weakened by the fact that propranolol's action involves the competitive blockade of a highly variable physiologic system. Thus, a variable response to the drug may reflect differences in sympathetic activity, independent of the blood level of the drug.

The results of this study support the use of high doses of propranolol in patients with exertional angina who fail to respond adequately to medium-dose therapy. Despite only a small additional effect on hemodynamic features and quantitative indexes of myocardial ischemia, high-dose propranolol may be of additional benefit in relieving ischemia and improving symptoms, without a significant risk of inducing LV failure in subjects with normal or near normal LV function.

Anatomic and Prognostic Significance of New T-Wave Inversion in Unstable Angina

DAVID E. HAINES, MD, DANIEL S. RAABE, MD, WALTER D. GUNDEL, MD, and FRANS J. Th. WACKERS, MD

The significance of the development of new T-wave inversion was studied in 118 consecutive patients with unstable angina. The electrocardiograms during hospitalization in the coronary care unit were analyzed for occurrence of new T-wave inversion ≥2 mm and correlated with findings at coronary angiography (73 patients) and at follow-up (112 patients). Twenty-nine patients had anterior T-wave inversion. Of these, 25 patients (86%) had ≥70% diameter reduction of the left anterior descending (LAD) artery, compared with 11 (26%) of 42 patients without anterior T-wave inversion ($p < 0.001$). The sensitivity of T-wave inversion for significant LAD stenosis was 69%, specificity 89%, and positive predictive value 86%. Two patients had T-wave inversion in the inferior leads. Both patients had significant right coronary artery disease, compared with 18 of 55 patients without inferior T-wave inversion (difference not significant [p = NS]. Seventy-one patients who were treated medically had 16 ± 9 months' follow-up. Of 26 patients who had T-wave inversion, 10 (38%) had cardiac events, compared with 7 (16%) of the remaining 45 patients without T-wave inversion ($p < 0.05$). Forty-one patients who had undergone coronary bypass surgery had 19 ± 9 months' follow-up. Of 22 patients with T-wave inversion, 4 (18%) had cardiac events, compared with 2 (11%) of the remaining 19 patients without T-wave inversion (p = NS).

Thus, development of new T-wave inversion ≥2 mm in patients with unstable angina (1) is predictive of significant coronary artery stenosis, and (2) identifies a subgroup with poor prognosis when treated medically.

During hospital observation, patients with unstable angina may develop new T-wave inversion on the electrocardiogram, without associated increase and decrease of cardiac enzymes. Although transient ST-T segment changes during episodes of angina pectoris are well recognized as reflections of acute myocardial ischemia,[1–8] the significance of the gradual development of T-wave inversion associated with symptoms of unstable angina is less well understood. Recently, it has been suggested that this characteristic electrocardiographic pattern is associated with a particularly poor prognosis.[9] The purpose of the present study was 2-fold: (1) to define the pathoanatomic correlation of new T-wave inversion in patients with unstable angina, in particular the distribution and severity of coronary artery disease; and (2) to analyze the potential prognostic implications of this finding in medically and surgically treated patients.

From the University of Vermont, College of Medicine, Department of Medicine, Cardiology Section, Burlington, Vermont. Manuscript received November 11, 1982; revised manuscript received April 11, 1983, accepted April 12, 1983.

Methods

Patient group: The electrocardiograms and medical records of 146 consecutive patients, discharged from the coronary care unit in the period from March 1980 to August 1982 with the diagnosis of unstable angina, were reviewed. Unstable angina was defined as new or recent (<1 month) onset of typical angina pectoris brought on by minimal exertion or at rest, or recent exacerbation of previously stable typical exertional angina pectoris.

All patients were in the coronary care unit for at least 48 hours. Cardiac enzymes (creatine kinase, creatine kinase isoenzymes, lactic dehydrogenase isoenzymes, and serum glutamic oxaloacetic transaminase) were obtained on admission and every 6 hours for 48 hours. No patient had enzymatic documentation of myocardial infarction (MI) according to the criteria of the New York Heart Association.[10]

Twenty-eight patients were excluded from further analysis: 12 patients who had had acute MI <2 weeks before readmission to the coronary care unit, 14 patients with either complete left or right bundle branch block, and 1 patient with previous transmural anterior and inferior MI. The remaining 118 patients are the study group.

Treatment groups: The patients were classified into 3 groups: Group A, 42 patients (28 men, 16 women, mean age 60 years) who underwent coronary angiography and subsequently had coronary artery bypass surgery; Group B, 31 patients (16 men, 15 women, mean age 56 years) who also underwent coronary angiography but were subsequently treated medically because findings at coronary angiography revealed either nonsurgical coronary artery disease, insignificant coronary artery disease, or normal coronary arteries; and Group C, 45 patients (34 men, 11 women, mean age 62 years) who did not undergo coronary angiography for reasons of age, resolution of symptoms after intensive medical therapy with nitrates, beta-blocking agents, and/or calcium-channel blocking drugs, or presence of underlying disease that precluded surgery. It should be emphasized that because of the retrospective nature of the present study, allocation of patients to each treatment group was not affected by the presence or absence of T-wave inversion on the electrocardiogram.

Electrocardiograms: All 12-lead electrocardiograms were obtained using standard lead placement and either a Cambridge model 3038/2S or model VS 4 electrocardiographic recorder (Cambridge Instruments, Ossining, New York). Serial electrocardiograms were obtained on admission to the coronary care unit and daily thereafter for at least 2 days. Supplemental electrocardiograms were obtained during episodes of chest pain. The electrocardiographic T-wave inversion analyzed in the present study fulfilled all of the following criteria: (1) a new finding on or after coronary care unit admission in comparison to previous electrocardiograms (patients without previous electrocardiograms for comparison were not entered in the study, unless they presented with new symptoms of unstable angina); (2) a sustained (>24 hours) electrocardiographic finding, that is, not a transient phenomenon associated with pain only; (3) ≥2 mm in amplitude from the isoelectric line; (4) T-wave inversion present in ≥2 of the anterior leads (I, aVL, V2 to V6) and/or in ≥2 of the inferior leads (II, III, and aVF), without evidence of previous MI in the leads analyzed.

Evidence of previous anterior MI was defined as presence of Q waves >0.04 second duration in any of leads I, aVL, and V_2 to V_6, and of previous inferior MI as a presence of Q wave >0.03 second duration in lead II or aVF.[10]

The electrocardiograms were analyzed independently by 2 observers without knowledge of coronary angiographic findings or clinical outcome. Between the 2 observers, complete agreement existed on 115 of 118 electrocardiograms. On the remaining 3, a consensus was reached.

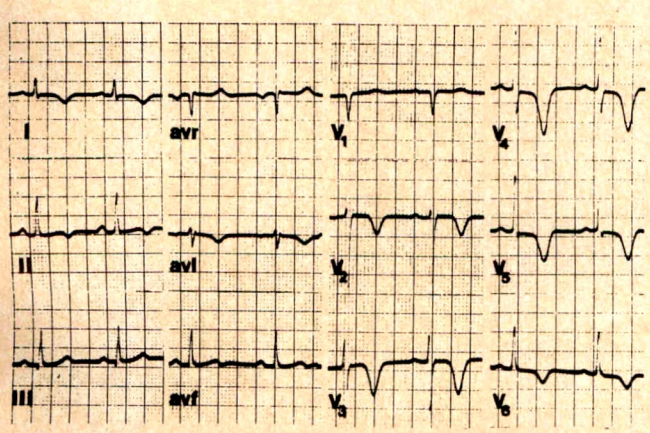

FIGURE 1. Symmetrical T-wave inversion with isoelectric S-T segment.

Electrocardiographic study groups: In the present study, the significance of the presence or absence of new T wave inversion was evaluated only in leads without evidence of previous MI. Electrocardiographic evidence of previous anterior MI was present in 8 patients, and of previous inferior MI in 21 patients. Therefore, the anterior leads were examined in a total of 110 patients (41 in Group A, 30 in Group B, and 39 in Group C), whereas the inferior leads were examined in a total of 97 patients (34 in Group A, 23 in Group B, and 40 in Group C).

Coronary angiography: Coronary angiography was performed using the Judkins or Sones technique. Multiple projections of selective coronary angiograms were obtained. Arteriograms were analyzed by at least 2 independent experienced observers without knowledge of electrocardiographic findings. Significant stenosis of a coronary artery was defined as ≥70% reduction of the luminal diameter determined by visual inspection. The dominant coronary artery supplying the inferior wall was noted. Left anterior descending (LAD) disease in the present study is defined as disease of the LAD or a major diagonal branch supplying blood flow to the anterior wall of the left ventricle.

Follow-up: Follow-up data on patients were obtained from private physicians' records, hospital records, or telephone interviews with the patients. MI during the follow-up period was defined as enzymatically and/or electrocardiographically documented MI. Death was assumed to be of cardiac origin if it was instantaneous, if the patient had complained of chest pain immediately before death, or if the patient died of cardiogenic shock or arrhythmia in a post-MI course.

Statistical methods: Statistical analysis was performed using the chi-square test. For analysis of series of proportions, the test for linear trend among proportions was utilized.[11] A p value <0.05 was considered statistically significant. Sensitivity is defined as true positives (TP) divided by false negatives (FN) + TP × 100; specificity is defined as true negatives (TN) divided by TN + false positives (FP) × 100; positive predictive value is defined as TP divided by TP + FP × 100.

Results

Electrocardiography: Overall, new T-wave inversion ≥2 mm occurred in 47 (40%) of 118 patients. Twenty patients had normal electrocardiograms on admission and subsequently developed T-wave inversion. In the remaining 27 patients, T-wave inversion was either a definite new finding compared with a recent electrocardiogram (15 patients), or was considered a new finding because the symptoms of unstable angina occurred anew (12 patients). The prevalence of new T-wave inversion was not significantly different among the 3 patient treatment groups: 20 (47%) of 42 patients in Group A, 11 (35%) of 31 patients in Group B, and 16 (36%) of 45 patients in Group C (p = NS). Of the 110 patients without previous anterior MI, new anterior T-wave inversion occurred in 41 (37%). Of the 97 patients without previous inferior MI, new inferior T-wave inversion occurred in 6 (6%) patients. Three predominant configurations of T-wave inversion were observed, although transition from one form to another on the same or serial electrocardiograms was noted. The most common form was symmetrical inversion with isoelectric S-T segment (Fig. 1). The second form was biphasic with the inverted portion >2 mm from the

isoelectric line (Fig. 2). Finally, T-wave inversion was noted in association with S-T segment depression (Fig 3).

Coronary angiography: Of the 73 patients who underwent coronary angiography (Group A and B), 56 had ≥70% stenosis of 1 or more coronary arteries. Twenty-seven had single-vessel, 15 had double-vessel, and 14 had triple-vessel disease. Of the remaining 17 patients, 3 patients had 50 to 70% stenosis of a single coronary artery, 2 patients had <50% stenosis of 1 vessel, and 12 patients had no evidence of coronary artery disease. Two patients had previous anterior MI, and 16 patients had previous inferior MI. The 31 patients comprising Group B were not considered for surgery for varying reasons. Fifteen patients had insignificant coronary artery disease and 8 patients had single-vessel disease only. Three patients had double-vessel disease and 5 patients had triple-vessel disease; however, they had such severe distal disease that grafting was judged not technically feasible.

New T-wave inversion and coronary artery anatomy: Thirty-one of the patients who had coronary angiography had new T-wave inversion, 27 (87%) of these had significant coronary artery disease, compared with 26 of 42 patients without new T-wave inversion ($p < 0.01$).

Anterior T-wave inversion: New T-wave inversion in the anterior leads was evaluated as a predictor of LAD disease in 71 patients without previous anterior MI. Of 29 patients with new T-wave inversion, 25 (86%) had ≥70% stenosis of the LAD. Of 42 patients without new T-wave inversion, only 11 (26%) had significant LAD stenosis ($p < 0.0001$) (Fig. 4). For the detection of LAD disease, the anterior leads V_2 to V_6 were most important: no patients with T-wave inversion in lead I or aVL had normal anterior leads. Thus, new T-wave inversion ≥2 mm in the anterior leads had a positive predictive value of 86% (25 of 29), a sensitivity of 69% (25 of 36), and a specificity of 89% (31 of 35) for significant LAD disease.

Four patients who had new T-wave inversion had no significant LAD disease. Three of these had normal coronary arteries. All had resolution of their anginal symptoms in the follow-up period without any antianginal medical therapy. The remaining patient had significant narrowing of the left circumflex artery. During the 28 month follow-up period, this patient continued to have anginal symptoms, despite eventual single-vessel coronary artery bypass grafting.

Inferior T-wave inversion: New T-wave inversion in the inferior leads was analyzed as a predictor for dominant right coronary artery or dominant left circumflex artery disease in 57 patients without previous inferior MI. Only 2 of 57 patients had new T-wave inversion. Both had ≥70% stenosis of the dominant artery supplying the inferior wall of the left ventricle. In comparison, 18 of 55 patients without inferior lead T-wave inversion had comparable significant disease (p = NS). Thus, although new T-wave inversion in the inferior leads appears to be specific for dominant right coronary artery or left circumflex artery disease, the sensitivity is low (10%).

Amplitude of T-wave and severity of stenosis: As discussed earlier, of 42 patients without T-wave inversion in the anterior leads, 11 patients (26%) had ≥70% LAD stenosis. In contrast, of 29 patients with ≥2 mm T-wave inversion in the anterior leads, 25 (86%) had significant LAD disease. Of 21 patients with ≥3 mm T-wave inversion, 17 (81%) had significant LAD stenosis, and 13 (81%) of 16 patients with ≥4 mm T-wave inversion had this finding (p = NS). Thus, an increased amplitude of negative T waves was not associated with higher prevalence of disease. Similarly, no correlation existed between the amplitude of negative T waves and the severity of LAD stenosis. Greater than 90% stenosis of the LAD artery occurred in 9 (66%) of 29 patients with ≥2 mm T-wave inversion, in 13 (62%) of 21 patients with ≥3 mm T-wave inversion and 12 (75%) of 16 patients with ≥4 mm T-wave inversion (p = NS).

New T-wave inversion and number of diseased coronary arteries: New T-wave inversion in the anterior leads correlates well with the presence of significant LAD disease. Of a total of 71 patients, 36 had LAD disease. Of these, 10 of 14 patients with single-vessel LAD disease, 4 of 9 patients with double-vessel disease, and 11 of 13 patients with triple-vessel disease had new T-wave inversion in the anterior leads (p = NS). Thus,

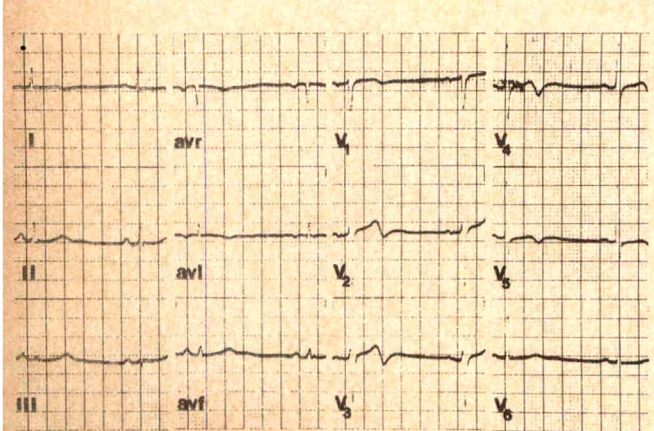

FIGURE 2. Biphasic T-wave inversion.

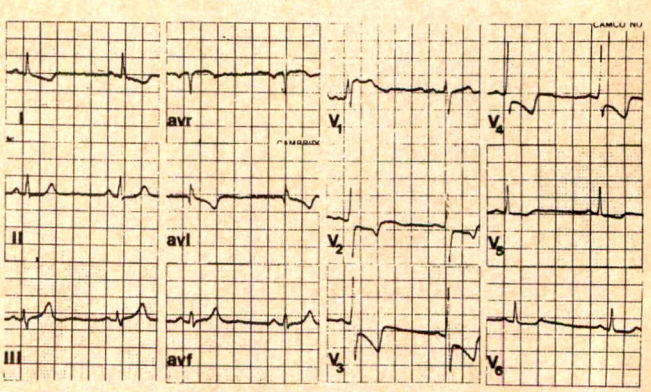

FIGURE 3. T-wave inversion associated with S-T segment depression.

the presence of new T-wave inversion is not predictive for number of vessels involved.

Follow-up: *Medical treatment:* A total of 76 patients (Groups B and C) were treated medically with beta-adrenergic blocking agents, nitrates, and/or calcium channel antagonists. Five patients were lost to follow-up. The remaining 71 patients had follow-up for 16 ± 9 months. Twenty-six patients had new T-wave inversion: 20 in anterior leads, 4 in inferior leads, and 2 in both anterior and inferior leads. During the follow-up period, 10 (38%) of 26 patients had either acute MI (3 patients) or cardiac death (7 patients, 27%). Of these 10 patients, 6 had anterior T-wave inversion, 3 inferior T-wave inversion, and 1 both inferior and anterior T-wave inversion. In contrast, only 7 (16%) of 45 patients without new T-wave inversion on the electrocardiogram during the hospital stay had acute MI (4 patients) or cardiac death (3 patients) during the follow-up period ($p < 0.05$) (Fig. 4). The mean length of time between coronary care unit hospitalization and cardiac event in follow-up was 6 ± 3 months in the 10 patients with new T-wave inversion, and 14 ± 6 months in the 7 patients without new T-wave inversion.

Coronary bypass surgery: Of 42 patients who underwent coronary bypass surgery (Group A), 1 was lost to follow-up and the remaining 41 patients had 19 ± 9 months (mean ± standard deviation) follow-up. During the preoperative stay in the coronary care unit, 22 patients had new T-wave inversion (20 in anterior leads and 2 in inferior leads). Four (18%) of the patients with T-wave inversion had either MI (2 perioperative and 1 seven months after operation) or cardiac death (1 perioperative). Of 19 patients without T-wave inversion, 2 (11%) had perioperative MI (p = NS). The incidence of cardiac events was not different (p = NS) from that in patients without T-wave inversion who were treated medically.

Discussion

The results of our study indicate that, among patients with unstable angina, the electrocardiographic development of new T-wave inversion in the anterior leads identifies a subgroup of patients with high prevalenc of significant LAD stenosis. Also, the subgroup with nev T-wave inversion appears to be at high risk for subse quent MI and cardiac death. A high incidence of cardia events occurred in patients who initially seemed to re spond favorably to intensive medical treatment. Ou findings corroborate in a larger group of patients, witl and without new T-wave inversion, the prognostic in formation to be gained from the surface electrocardio gram as reported by Zwaan et al.[9] These investigator included only patients with T-wave inversion in pre cordial leads V_2 and V_3, which may in part explain th lower prevalence (18%) of T-wave inversion and th extremely high incidence (70%) of cardiac events compared with that in our series.

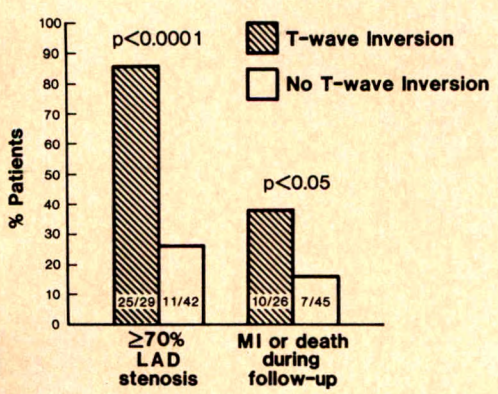

FIGURE 4. Prevalence of significant left anterior descending coronary artery stenosis and the incidence of cardiac events in patients with and without new T-wave inversion. LAD = left anterior descending coronary artery; MI = myocardial infarction.

Previous studies on unstable angina, as a rule, eithe did not separately analyze the patients with T-wav inversion and/or required electrocardiographic change as entrance criteria to their study group.[1–8,12] Currently the management of individual patients with unstabl angina may vary considerably in different centers. Ir some, immediate coronary angiography and grafting o the coronary arteries is recommended, whereas in other a more conservative attitude is taken. As a rule, th electrocardiogram is employed only as additional ob jective clinical evidence of myocardial ischemia wher transient ST-T segment changes occur, particularly during pain. The decision to proceed with coronary angiography and subsequent coronary bypass surgery usually is predominantly based on failure of medica treatment, rather than electrocardiographic findings The potential prognostic value of electrocardiograms in patients with unstable angina only recently has beer appreciated.[8,9,13] Our study demonstrates that not only deep negative T waves (Fig. 1) but also less impressive T-wave inversions correlate with significant stenosis o the LAD.

New negative T-wave inversion in the inferior leads occurred less frequently in our study and appeared to have less clinical value than precordial T-wave changes Nevertheless, the 2 patients with new T-wave inversion in the inferior leads both had significant stenosis of the dominant artery supplying the inferior wall. This ap pears to indicate that the electrocardiographic location of new negative T-wave inversion correlates with the anatomic location of severe coronary artery stenosis The underlying pathophysiologic mechanism of the occurrence of electrocardiographic negative T waves is incompletely understood. Reversible electrocardio graphic findings associated with ischemia are often thought of as transient phenomena that resolve imme diately as ischemia is diminished. Myocardial ischemia involving the subepicardial area may alter and reverse the pathway of electrical repolarization resulting in inverted T-wave morphology.[14,15] The fact that the T-wave inversion lingers after resolution of symptoms implies structural or biochemical alteration of the myocardium.

Myocardial perfusion defects on thallium-201 scintigrams, suggesting myocardial ischemia, have been demonstrated in 40% of patients with unstable angina even during the pain-free period.[16] Donsky et al[17] re-

ported abnormal technetium-99m–pyrophosphate myocardial scintigrams in approximately one third of patients with unstable angina in the absence of enzymatic or electrocardiographic evidence of acute MI. Clinical-pathologic correlation in these patients demonstrated scattered foci of myocardial necrosis.[18] In patients with unstable angina the distinction between severe ischemia and small nontransmural MI is an artificial one. In this light, the poor long-term prognosis of patients with new T-wave inversion in unstable angina is similar to that of patients with nontransmural MI, who have increased posthospital discharge mortality and complications.[19,20]

Clinical implications: A recent report of a prospective study by Hultgren et al[21] examining medical versus surgical therapy in unstable angina showed a small improvement in survival of those undergoing coronary artery bypass surgery compared with those receiving medical therapy. Early cardiac catheterization and surgery in patients with unstable angina is being advocated by some groups.[22,23] There clearly is a need to define more precisely high-risk subgroups that could benefit most from surgery.

In patients with unstable angina, the development of new T-wave inversion on the electrocardiogram provides important prognostic information, heralding increased incidence of MI and cardiac death. Although the number of patients is relatively small and bias in patient selection cannot be excluded, the significantly lower incidence of cardiac events in patients who underwent coronary bypass surgery, compared with that in patients treated medically, suggests that this subgroup in particular benefits from a more aggressive approach. Further studies should explore results of medical versus surgical therapy in this high-risk subgroup.

New and important evidence affirms the

Slow-K®

potassium chloride slow-release tablets 8 mEq

8-year U.S. record of clinical experience.

Please see last page for brief Prescribing Information.

New endoscopic studies show:

No significant difference in GI lesions between

Slow-K®
potassium chloride slow-release tablets 8 mEq

and

Micro-K®
potassium chloride controlled-release Extencaps® 600 mg 8 mEq K

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

Maximum-dosage (96 mEq) multistudy data*

Results: No significant differences in endoscopic changes found between Slow-K and Micro-K at 96-mEq dosage.†

(Administered as four 8-mEq tablets or capsules, t.i.d.)

These data resulted from four different studies (involving 64 subjects) that used the maximum recommended daily dosage of 96 mEq before food ingestion and with concomitant administration of the maximum recommended dosage of the anticholinergic agent glycopyrrolate (6 mg).[1-4]

Maximum-dosage multistudy data

					Endoscopic findings ‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
27	Slow-K	96 mEq	6 mg	No	1	1	6	12
37	Micro-K	96 mEq	6 mg	No	2	1	2	9

Results from similar studies supported by the A.H. Robins Company have shown a greater incidence of endoscopically observed GI irritation with Slow-K as compared to Micro-K when maximum doses of glycopyrrolate are administered.[5,6] These results, showing a significant difference between the products, are *inconsistent* with the data described herein, which do not show a significant difference.

High-dosage (48 mEq) multistudy data*

Results: No ulcers found with Slow-K or Micro-K. No significant differences in endoscopic changes found with Slow-K and Micro-K at 48-mEq dosage.

(Administered as two 8-mEq tablets or capsules, t.i.d.)

These data resulted from two different studies (involving 36 subjects) that used the high (48 mEq) dosage with food ingestion, and with and without the maximum recommended dosage of the anticholinergic agent glycopyrrolate. (Note: Glycopyrrolate was used in only one group of subjects on Slow-K.)[1,2] This 48-mEq dosage is higher than that normally used prophylactically.

High-dosage multistudy data

					Endoscopic findings ‡			
N	Treatment	Daily dosage	Glycopyrrolate	Food	Ulcers	3	2	1
12	Slow-K	48 mEq	6 mg	Yes	0	0	2	6
12	Slow-K	48 mEq	None	Yes	0	0	0	4
12	Micro-K	48 mEq	None	Yes	0	0	1	5

*These studies were conducted by Drs. D. Patterson and G. Jeffries of the Hershey Medical Center, and by Dr. D. Earnest of the University of Arizona (Tucson).

†Also included in these multistudy data were an additional 70 subjects taking an 8-mEq sustained-release KCl capsule, a K^+ elixir, a sustained-release KCl tablet of higher mEq dosage than that currently available, or a placebo. The elixir and the placebo did not produce any endoscopic changes greater than two Grade 1 and five Grade 1 endoscopic findings, respectively. The higher dose sustained-release KCl tablets produced two ulcers, two Grade 2 and six Grade 1 endoscopic findings. The 8-mEq sustained-release capsule produced two Grade 2 and two Grade 1 findings. All Grade 1 endoscopic changes were considered clinically meaningless.

‡Grade 0 = no endoscopic findings
1 = hyperemia and/or edema (the medical consensus is that this category is clinically meaningless)
2 = few erosions
3 = numerous erosions (>3)
4 = ulceration
5 = multiple ulcerations

The anticholinergic agent glycopyrrolate was given to slow gastric emptying, thus ensuring maximum contact of the KCl supplements with the gastric mucosa. The impact, if any, of high-dose glycopyrrolate on the gastric mucosa is unknown.

Please see last page for brief Prescribing Information.

CIBA

New epidemiologic study shows:

No difference between

Slow-K®

potassium chloride slow-release tablets 8 mEq

use and no K^+ therapy in the incidence of upper GI bleeding in a hospital setting.

SLOW-K: UNSURPASSED FOR SAFETY AMONG SLOW-RELEASE KCl CAPSULES OR TABLETS

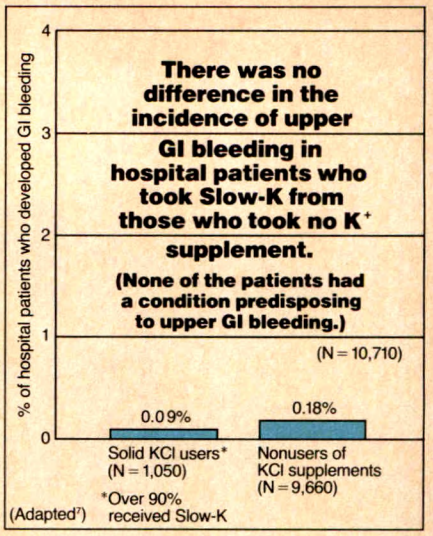
Experience of the Boston Collaborative Drug Surveillance Program[7]
As reported by Aselton and Jick in *Lancet,* January 22, 1983

Purpose of epidemiologic study:
To evaluate the relation between the use of wax-matrix KCl and the development of upper GI bleeding while in the hospital.

Patient population:
A total of 15,791 medical inpatients. Of those, 10,710 had no condition predisposing to upper GI bleeding. Of those, 1,050 received solid KCl* by mouth; 9,660 received no solid KCl.

Findings:
Of the 1,050 KCl users, 1 had GI bleeding (0.09%).
Of the 9,660 nonusers, 17 had GI bleeding (0.18%).

*Over 90% of this group received KCl in the form of Slow-K tablets.



(Adapted[7])

Conclusion: "These findings argue against a positive association between wax matrix KCl use and upper gastrointestinal bleeding over a short period of time."[7]

These new data are consistent with the overwhelming evidence compiled in 8 years of use with Slow-K® potassium chloride slow-release tablets 8 mEq.

Analysis of 5.6 million U.S. patient-years' data: approximately one GI lesion per 100,000 patient-years—and this incidence rate has remained unchanged since Slow-K was introduced in 1975.[8]

*Method of determining incidence:
A: Includes all cases (most conservative method)
B: Excludes cases in which causality was unlikely and/or Slow-K was contraindicated
C: Excludes cases in which B was present *and* in which data were insufficient to assess causality (least conservative method)

Summary of lesion incidence rates per 100,000 patient-years

	Method* A	B	C
Esophagus	0.14	0.02	0.02
Stomach	0.27	0.14	0.11
Duodenum	0.12	0.05	0.05
Small bowel/large bowel; unknown location	0.82	0.43	0.27
Total	1.36	0.64	0.44

(Adapted[8])

Conclusion: Slow-K is a safe agent.

Capsule or tablet slow-release potassium chloride preparations should be reserved for patients who cannot tolerate, refuse to take or have compliance problems with liquid or effervescent potassium preparations, because of reports of intestinal and gastric ulceration and bleeding with slow-release KCl preparations.

Please see last page for brief Prescribing Information.

SLOW-K®
potassium chloride **slow-release tablets**

Brief Summary of Prescribing Information

DESCRIPTION
Slow-K is a sugar-coated (not enteric-coated) tablet containing 600 mg potassium chloride (equivalent to 8 mEq) in a wax matrix. This formulation is intended to provide a controlled release of potassium from the matrix to minimize the likelihood of producing high localized concentrations of potassium within the gastrointestinal tract.

INDICATIONS
BECAUSE OF REPORTS OF INTESTINAL AND GASTRIC ULCERATION AND BLEEDING WITH SLOW-RELEASE POTASSIUM CHLORIDE PREPARATIONS, THESE DRUGS SHOULD BE RESERVED FOR THOSE PATIENTS WHO CANNOT TOLERATE OR REFUSE TO TAKE LIQUID OR EFFERVESCENT POTASSIUM PREPARATIONS OR FOR PATIENTS IN WHOM THERE IS A PROBLEM OF COMPLIANCE WITH THESE PREPARATIONS.
1. For therapeutic use in patients with hypokalemia with or without metabolic alkalosis; in digitalis intoxication and in patients with hypokalemic familial periodic paralysis.
2. For prevention of potassium depletion when the dietary intake of potassium is inadequate in the following conditions: Patients receiving digitalis and diuretics for congestive heart failure; hepatic cirrhosis with ascites; states of aldosterone excess with normal renal function; potassium-losing nephropathy, and certain diarrheal states.
3. The use of potassium salts in patients receiving diuretics for uncomplicated essential hypertension is often unnecessary when such patients have a normal dietary pattern. Serum potassium should be checked periodically, however, and, if hypokalemia occurs, dietary supplementation with potassium-containing foods may be adequate to control milder cases. In more severe cases supplementation with potassium salts may be indicated.

CONTRAINDICATIONS
Potassium supplements are contraindicated in patients with hyperkalemia since a further increase in serum potassium concentration in such patients can produce cardiac arrest. Hyperkalemia may complicate any of the following conditions: chronic renal failure, systemic acidosis such as diabetic acidosis, acute dehydration, extensive tissue breakdown as in severe burns, adrenal insufficiency, or the administration of a potassium-sparing diuretic (*eg*, spironolactone, triamterene).
Wax-matrix potassium chloride preparations have produced esophageal ulceration in certain cardiac patients with esophageal compression due to an enlarged left atrium.
All solid dosage forms of potassium supplements are contraindicated in any patient in whom there is cause for arrest or delay in tablet passage through the gastrointestinal tract. In these instances, potassium supplementation should be with a liquid preparation.

WARNINGS
Hyperkalemia: In patients with impaired mechanisms for excreting potassium, the administration of potassium salts can produce hyperkalemia and cardiac arrest. This occurs most commonly in patients given potassium by the intravenous route but may also occur in patients given potassium orally. Potentially fatal hyperkalemia can develop rapidly and be asymptomatic.
The use of potassium salts in patients with chronic renal disease, or any other condition which impairs potassium excretion, requires particularly careful monitoring of the serum potassium concentration and appropriate dosage adjustment.
Interaction with Potassium-Sparing Diuretics: Hypokalemia should not be treated by the concomitant administration of potassium salts and a potassium-sparing diuretic (*eg*, spironolactone or triamterene), since the simultaneous administration of these agents can produce severe hyperkalemia.
Gastrointestinal lesions: Potassium chloride tablets have produced stenotic and/or ulcerative lesions of the small bowel and deaths. These lesions are caused by a high localized concentration of potassium ion in the region of a rapidly dissolving tablet, which injures the bowel wall and thereby produces obstruction, hemorrhage, or perforation. Slow-K is a wax-matrix tablet formulated to provide a controlled rate of release of potassium chloride and thus to minimize the possibility of a high local concentration of potassium ion near the bowel wall. While the reported frequency of small-bowel lesions is much less with wax-matrix tablets (less than one per 100,000 patient-years) than with enteric-coated potassium chloride tablets (40-50 per 100,000 patient-years) cases associated with wax-matrix tablets have been reported both in foreign countries and in the United States. In addition, perhaps because the wax-matrix preparations are not enteric-coated and release potassium in the stomach, there have been reports of upper gastrointestinal bleeding associated with these products. The total number of gastrointestinal lesions remains approximately one per 100,000 patient-years. Slow-K should be discontinued immediately and the possibility of bowel obstruction or perforation considered if severe vomiting, abdominal pain, distention, or gastrointestinal bleeding occurs.
Metabolic acidosis: Hypokalemia in patients with metabolic *acidosis* should be treated with an alkalinizing potassium salt such as potassium bicarbonate, potassium citrate, or potassium acetate.

PRECAUTIONS
The diagnosis of potassium depletion is ordinarily made by demonstrating hypokalemia in a patient with a clinical history suggesting some cause for potassium depletion. In interpreting the serum potassium level, the physician should bear in mind that acute alkalosis *per se* can produce hypokalemia in the absence of a deficit in total body potassium, while acute acidosis *per se* can increase the serum potassium concentration into the normal range even in the presence of a reduced total body potassium. The treatment of potassium depletion, particularly in the presence of cardiac disease, renal disease, or acidosis, requires careful attention to acid-base balance and appropriate monitoring of serum electrolytes, the electrocardiogram, and the clinical status of the patient.

ADVERSE REACTIONS
The most common adverse reactions to oral potassium salts are nausea, vomiting, abdominal discomfort, and diarrhea. These symptoms are due to irritation of the gastrointestinal tract and are best managed by diluting the preparation further, taking the dose with meals, or reducing the dose.
One of the most severe adverse effects is hyperkalemia (see Contraindications, Warnings and Overdosage). There also have been reports of upper and lower gastrointestinal conditions including obstruction, bleeding, ulceration and perforation (see Contraindications and Warnings); other factors known to be associated with such conditions were present in many of these patients. Skin rash has been reported rarely.

DOSAGE AND ADMINISTRATION
The usual dietary intake of potassium by the average adult is 40 to 80 mEq per day. Potassium depletion sufficient to cause hypokalemia usually requires the loss of 200 or more mEq of potassium from the total body store. Dosage must be adjusted to the individual needs of each patient but is typically in the range of 20 mEq per day for the prevention of hypokalemia to 40-100 mEq per day or more for the treatment of potassium depletion.
Note: Slow-K slow-release tablets must be swallowed whole and never crushed or chewed.

How thorough and unbiased is your drug reference?

If it's not MODERN DRUG ENCYCLOPEDIA, you can't be sure.

MODERN DRUG ENCYCLOPEDIA and Therapeutic Index 16th Edition

Arthur J. Lewis, MD, Executive Editor
Gertrude Dittus Gonzales, R.Ph., B.S. Pharm., Executive Editor
Charles L. Winek, Ph.D., Contributing Editor

The all new 16th Edition of MODERN DRUG ENCYCLOPEDIA is written especially for the practitioner who needs complete, objective information on prescription drugs.

An independent team of pharmacists and physicians has researched and edited all the facts on 3,000 prescription drugs. It passes this research on to you in an easy to absorb style that's perfectly suited to the tight schedule of a time pressed practitioner.

Some handbooks just reprint manufacturers' package inserts. They don't edit. Just print material manufacturer pays to have included.

Here's what careful planning does for MODERN DRUG ENCYCLOPEDIA:

- limits entries to prescription drugs. You don't waste time flipping through pages of extraneous drugs.
- lists over 3,000 pharmaceuticals, biologicals, and allergens in one a-z sequence.
- arranges entries by generic name. All brand names in one place.
- written in concise language for quick comprehension.
- designed with a "strong focus" layout, easy-to-read type, and bold subject headings.

The 1,000 page main section arranges over 3,000 drugs alphabetically by generic name. Each entry covers vital facts about brand names and each manufacturer that markets their own brand.

Three a-z indexes provide instant access to all the material found in the main section as follows:

- GENERAL INDEX of all brand generic names in handy alphabetic sequence.
- THERAPEUTIC INDEX of which drugs are prescribed for which purpose. Allows you a wide selection of therapy based on your patient's special needs.
- MANUFACTURERS INDEX of names and addresses and product names. Helps you identify the drug when you only know the manufacturer's name.

Try using MODERN DRUG ENCYCLOPEDIA for 30 days at our risk. Then keep it only if you're convinced that it answers a practitioner's need for concise, easy to read information on prescription drugs.

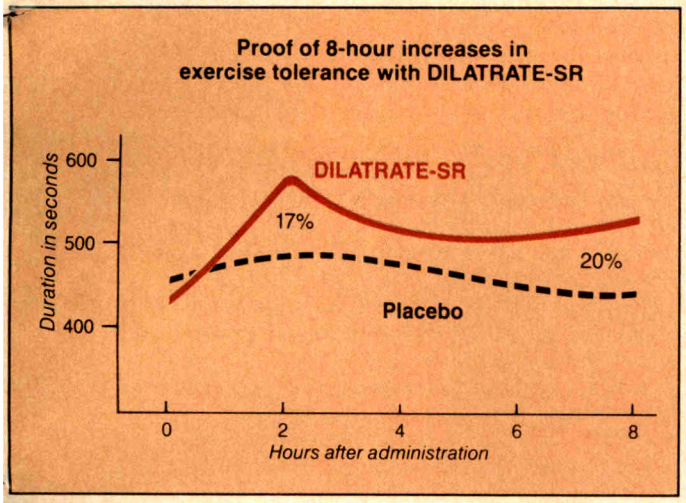
HAS CLINICAL

In treadmill tests, DILATRATE-SR produced a 17% increase in mean total exercise duration within 2 hours; after 8 hours the increase was 20%.



*Exercise duration and work capacity increased for a full 8 hours in angina patients**

In a double-blind, placebo-controlled study involving patients with chronic stable angina, significant improvement in exercise capacity was sustained for eight hours following administration of one 40 mg DILATRATE-SR capsule.[1]

This is the first study to demonstrate that a sustained-release nitrate formula can provide clinical effectiveness for a full eight hours. And, the advantage over placebo did not appear to be decreasing at the end of eight hours.

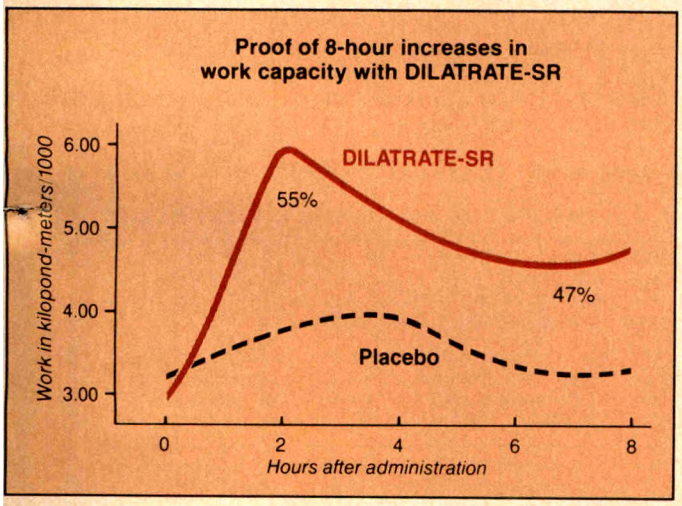
Increases in exercise tolerance translate into true patient benefits

Exercise tolerance tests provide objective measurements of improvement in work capacity that can be correlated with the anginal patient's daily activities. These results demonstrate that DILATRATE-SR can provide a positive impact on your patient's lifestyle.

Clinical support of plasma level studies

This clinical study supports previous blood assays which demonstrated that DILATRATE-SR provides significant plasma levels of ISDN for up to 12 hours.[2]

PROOF: 8-hour antianginal activity*



A 20% increase in duration of treadmill exercise means another minute or two at higher speed on a steeper incline. When mean work performance was calculated, DILATRATE-SR provided a 47% increase at 8 hours.

A unique method of delivering isosorbide dinitrate

DILATRATE-SR employs a unique delivery system — an advanced microdialyzing membrane that releases ISDN at a steady rate independent of gastric pH and enzymes. The water-activated membrane continually adjusts permeability to maintain constant nitrate release.

DILATRATE-SR simplifies antianginal therapy

The proven sustained activity of DILATRATE-SR offers anginal patients convenient b.i.d. dosage and can reduce the need for sublingual nitroglycerin.

Dilatrate®-SR
(isosorbide dinitrate) 40 mg

BRIEF SUMMARY

Indications: Based on a review of this drug by the National Academy of Sciences – National Research Council and/or other information, FDA has classified the indications as follows:

"Possibly" effective: When taken by the oral route, is indicated for the relief of angina pectoris (pain of coronary artery disease). It is not intended to abort the acute anginal episode, but is widely regarded in the prophylactic treatment of angina pectoris.

Final classification of the less-than-effective indication requires further investigation.

CONTRAINDICATION: Idiosyncrasy to this drug.

WARNINGS: Data supporting the use of nitrates and nitrites during the early days of the acute phase of myocardial infarction (the period during which clinical and laboratory findings are unstable) are insufficient to establish safety.

PRECAUTIONS: Tolerance to this drug, and cross-tolerance to other nitrates or nitrites may occur.

In patients with functional or organic gastrointestinal hypermotility or malabsorption syndrome it is suggested that either the 5 mg. or 10 mg. oral tablets or 2.5 mg. or 5 mg. sublingual tablets be the preferred therapy.

ADVERSE REACTIONS: Cutaneous vasodilation with flushing. Headache is common and may be severe and persistent. Transient episodes of dizziness and weakness as well as other signs of cerebral ischemia associated with postural hypotension may occasionally develop. This drug can act as a physiological antagonist to norepinephrine, acetylcholine, histamine, and many other agents.

An occasional individual exhibits marked sensitivity to the hypotensive effects of nitrite, and severe responses (nausea, vomiting, weakness, restlessness, pallor, perspiration and collapse) can occur even with the usual therapeutic dose. Alcohol may enhance this effect. Drug rash and/or exfoliative dermatitis may occasionally occur.

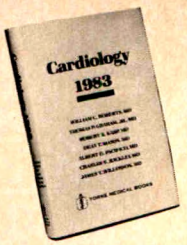
Cardiology 1983



The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

What is Cardiology 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, **written**, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

• William C. Roberts, MD • Thomas P. Graham, Jr., MD • Robert B. Karp, MD • Dean T. Mason, MD • Albert D. Pacifico, MD • Charles E. Rackley, MD • James T. Willerson, MD

Ventricular Tachyarrhythmias in Prinzmetal's Variant Angina: Clinical Significance and Relation to the Degree and Time Course of S-T Segment Elevation

MARIO PREVITALI, MD, CATHERINE KLERSY, MD, JORGE A. SALERNO, MD, MARCELLO CHIMIENTI, MD, CLAUDIO PANCIROLI, MD, EGIDIO MARANGONI, MD, GIUSEPPE SPECCHIA, MD, MARIO COMOLLI, MD, and PIERO BOBBA, MD

Fifty-six patients with active Prinzmetal's variant angina were studied to determine the incidence and clinical significance of ventricular tachyarrhythmias and the correlation between arrhythmias and degree and time course of S-T segment changes during the ischemic attacks. Twenty-nine patients (Group I) had no ventricular arrhythmias in any of the 1,083 recorded episodes, while 27 patients (Group II) developed arrhythmias in 18% of the attacks. No significant differences in clinical, electrocardiographic, angiographic, or hemodynamic findings could be found between the 2 groups. In 23 of the 27 Group II patients, ventricular arrhythmias developed during maximal S-T segment elevation (occlusion arrhythmias), while in 10 they occurred during resolution of S-T segment changes (reperfusion arrhythmias); 6 of the latter patients also had occlusion arrhythmias. Eight of the 23 patients with occlusion arrhythmias and 6 of the 10 with reperfusion arrhythmias had ventricular fibrillation or ventricular tachycardia. Maximal S-T segment elevation was significantly greater ($p < 0.001$) in patients with occlusion arrhythmias than in those without arrhythmias. The episodes with reperfusion arrhythmias were significantly longer ($p < 0.001$) and showed a significantly greater S-T segment elevation ($p < 0.001$) than those without arrhythmias in Group I patients.

This study shows that significant ventricular tachyarrhythmias develop during ischemic attacks in about 50% of patients with active variant angina; clinical and angiographic features are not useful in distinguishing patients with arrhythmias from the others. Our findings suggest that in variant angina ventricular arrhythmias may be due to the effects of both coronary artery occlusion and reperfusion; both types of arrhythmias are correlated with the severity of ischemia, as measured by the degree of S-T segment elevation. Reperfusion arrhythmias also appear to be correlated with the duration of ischemia.

It is well known that ventricular tachyarrhythmias may be associated with ischemic attacks in patients with Prinzmetal's variant angina pectoris.[1–5] The spectrum of reported arrhythmias includes ventricular tachycardia,[1,4,5] ventricular fibrillation,[2,4,5] and ventricular premature complexes.[3–5] However, only few data are available on the incidence and clinical significance of ventricular tachyarrhythmias in large groups of patients with Prinzmetal's variant angina. Moreover, the mechanisms of ventricular arrhythmias associated with ischemic attacks in these patients are still under investigation. Experimental studies have shown that both occlusion of a major coronary vessel and reperfusion of the ischemic region may trigger ventricular tachyarrhythmias.[6–13] Since reversible coronary artery spasm leading to transient coronary occlusion and subsequent reperfusion is well established as the cause of variant angina pectoris, the same mechanisms demonstrated in experimental animals could play a role in the pathogenesis of ventricular arrhythmias in patients with variant angina. Although occlusion and reperfusion phases cannot be directly identified in man, experimental and clinical studies have shown that coronary artery occlusion is associated with S-T segment elevation[12,14,15] and reperfusion with a rapid return of the S-T segment to baseline.[12,16] Therefore, continuous

Abbreviations as in Table I.

monitoring of S-T segment changes during the attacks may be of value in identifying occlusion and reperfusion phases in patients with variant angina pectoris.

The present study was designed to evaluate the incidence of ventricular tachyarrhythmias and their correlation with clinical and angiographic findings in a large group of subjects with variant angina who underwent continuous electrocardiographic monitoring in coronary care unit. A further purpose of the study was to correlate ventricular tachyarrhythmias with the degree and time course of S-T segment elevation, in order to determine their relation with severity of ischemia and occlusion and reperfusion phases.

Methods

Patient selection: Fifty-six patients, 52 men and 4 women aged 32 to 72 years (mean 54 ± 9) who had frequent attacks of angina at rest associated with transient S-T segment elevation, were selected for the study. Nineteen of them also had effort angina. Three patients had a history of an old myocardial infarction; 2 of them showed transient ischemic electrocardiographic changes in a region different from the infarcted one and 1 in the same region. No patient had symptoms or clinical signs suggestive of heart failure. The basal electrocardiogram was normal in 16 patients, while 33 patients showed nonspecific S-T segment changes and/or flat or negative T waves in the leads showing S-T segment elevation during the attacks. Q waves indicative of a previous myocardial infarction were present in 3 patients, incomplete right bundle branch block in 2 patients, left anterior hemiblock in 4 patients, and left ventricular hypertrophy in 1 patient.

Continuous electrocardiographic recording: All patients were admitted to the coronary care unit for continuous electrocardiographic monitoring; 41 underwent continuous electrocardiographic recording at a paper speed of 2.5 mm/s on a 6-channel recorder (Hellige Multiscriptor 9400/6) using leads I, II, III, V_2, V_4, and V_6; whenever possible during ischemic attacks recordings were obtained at a paper speed of 10 or 25 mm/s for detailed analysis. Fifteen patients underwent Holter monitoring with use of a 24-hour tape recorder (Oxford Medilog Mark I 4-24). In all these patients continuous multichannel electrocardiographic recording was carried out before Holter monitoring in order to detect the leads showing the most prominent alterations during acute ischemia. After skin preparation pregelled disposable electrodes were applied and carefully taped to avoid motion artifacts. A bipolar lead system was used: In patients with anterior S-T segment elevation 2 precordial leads (modified V_2 and V_5) were recorded and in those with inferior ischemia a lead exploring diaphragmatic wall (modified III) and a precordial lead were used. Before each recording period a 1 mV calibration signal was recorded using a Medilog XC-2 calibrator. Before the tapes were analyzed, the gain control of the replay unit was adjusted so that the 1 mV calibration signal previously recorded produced a 10-mm deflection on the chart recorder of the analyzer. The tapes were played back at 60 times real-time on a replay unit (Oxford PB-2) into an electrocardiographic analyzer (Pathfinder Medical Reynolds) with an S-T segment plotter. The analog output of heart rate and S-T segment were fed into a linear recorder at a paper speed of 6 cm/h of real-time recording. Whenever S-T segment shift from baseline occurred, whether or not associated with chest pain, the electrocardiogram was recorded at 25 mm/s. Ventricular arrhythmias were detected automatically by the analyzer and in each case printed out on chart and validated by the investigator. In order to carefully evaluate the time relation between S-T segment changes and ventricular arrhythmias, a tapes were also printed on photographic paper by means c a fiber optic full disclosure system (Eliminator 7700 America Edwards).

The duration of continuous electrocardiographic moni toring ranged from 1 to 132 hours (mean 36). During the in vestigation no patient was treated with vasodilators, digitalis beta-blocking agents, or antiarrhythmic drugs; sublingua nitroglycerin was administered as needed.

S-T segment elevation of at least 1 mm from the baselin lasting at least 1 minute whether or not associated with ches pain was considered indicative of acute myocardial ischemia S-T segment elevation was measured in millimeters 80 m after the J point, taking the P-R segment as a reference in th lead showing the highest S-T segment elevation. Duration o the episodes was calculated from the first changes of S-T segment or T wave to return of S-T segment to baseline. Fo the purpose of this study, the following ventricular arrhyth mias were taken into consideration: (1) frequent (defined a ≥5 beats/min), paired or multiform premature ventricula beats; (2) ventricular bigeminy or trigeminy; (3) ventricula tachycardia, defined as ≥3 consecutive premature ventricula beats at a rate of ≥130 beats/min; and (4) ventricular fibril lation. Isolated premature ventricular beats occurring durin ischemia and those already present in basal recordings wer excluded from the analysis. Ventricular arrhythmias occurrin during the waxing phase or at the peak of S-T segment ele vation were considered related to the occlusion phase an those developing during or immediately after return of the S-T segment to baseline related to the reperfusion phase.

Angiographic study: Of the 56 patients, 49 underwen coronary angiography by the Sones technique and left ven triculography. Stenosis of >50% of the vessel diameter wa considered significant. Left ventricular angiography wa carried out in the 30° right anterior oblique projection and th ejection fraction was calculated according to the Dodg method.

Statistical analysis: Mean values of S-T segment elevatio and duration of ischemia for the episodes with and withou ventricular arrhythmias were determined in each patient. A unpaired t test was used to compare these parameters i Group I (without arrhythmias) and Group II (with arrhyth mias) patients and a paired t test for comparison of the epi sodes with and without arrhythmias in Group II patients Differences in the prevalence of clinical and angiographi characteristics in patients with and without arrhythmias wer compared using either a chi-square test or the unpaired t tes when appropriate. A probability (p) value <0.05 was consid ered statistically significant. Data are expressed as means ± standard deviation.

Results

On the basis of the presence of ventricular tachyar rhythmias during the attacks, patients were classifie in 2 groups: Group I was composed of 29 patients wh never showed ventricular arrhythmias during acut ischemia; Group II was composed of 27 patients i whom ventricular arrhythmias were recorded in ≥ ischemic episodes. Individual clinical and angiographi findings are summarized in Table I for Group I patient and in Table II for Group II patients.

Comparison of clinical findings between patient with and without arrhythmias: The clinical, elec trocardiographic, hemodynamic, and angiographi findings in Group I patients are compared with thos in Group II patients in Table III. The age distributio

TABLE III Clinical, Electrocardiographic, Angiographic, and Hemodynamic Findings in Group I (Without Ventricular Arrhythmias) and Group II (With Ventricular Arrhythmias) Patients

	Group I	Group II
Patients (n)	29	27
Sex	26M (90%)	26M (96%)
	3F (10%)	1F (4%)

Ejection fraction (%) (mean ± SD)	59 ± 11	58 ± 9
LVEDP (mm Hg) (mean ± SD)	13 ± 4	13 ± 5

LVEDP = left ventricular end-diastolic pressure; SD = standard deviation.

and sex ratio were similar in the 2 groups. A history of previous infarction or effort angina and a normal electrocardiogram were found with similar frequency in the 2 groups. During the attacks S-T segment elevation in the anterior leads was more commonly documented in the patients with ventricular tachyarrhythmias, but the difference was not significant. No statistically significant differences were found in the extent of coronary lesions and basal left ventricular function between the 2 groups, although a greater proportion of patients with ventricular arrhythmias had normal or minimally diseased coronary arteries.

Relation between ventricular arrhythmias and time course and degree of S-T segment elevation: In Group I patients 1,083 ischemic attacks were recorded during 964 hours of continuous electrocardiographic monitoring (mean 33 ± 32); the mean duration of the attacks was 216 ± 189 seconds and the maximal S-T segment elevation during ischemia was 1.8 ± 1.0 mm.

Group II patients had 1,338 ischemic episodes during 1,039 hours of continuous electrocardiographic recording (mean 40 ± 29). Eighteen percent of the attacks were associated with arrhythmias. In 23 of these patients ventricular tachyarrhythmias developed close to or at the peak of S-T segment elevation (Fig. 1) and were considered occlusion arrhythmias, whereas in 10 patients arrhythmias appeared during or immediately after the return of the S-T segment to baseline (Fig. 2) and were classified as reperfusion arrhythmias; 6 of the latter patients also showed occlusion arrhythmias in the same or other ischemic attacks.

In the group with occlusion tachyarrhythmias 1 patient had ventricular fibrillation, 7 ventricular tachycardia, 8 ventricular bigeminy, 5 repetitive premature ventricular beats, and 2 frequent premature ventricular beats; the rate of ventricular tachycardia ranged from 132 to 280 beats/min (mean 190 ± 53). The mean duration of ischemic attacks was 494 ± 319 seconds; ventricular arrhythmias developed 180 ± 129 seconds after the beginning of ischemia. Maximal S-T segment elevation was significantly greater ($p < 0.001$) in the patients with occlusion ventricular arrhythmias than in Group I patients (Table IV). Eighteen of the 23 subjects with occlusion ventricular arrhythmias also had episodes without arrhythmias: the attacks associated with arrhythmias showed a significantly greater S-T segment elevation than did those without rhythm disturbances (6.3 ± 3.9 versus 3.5 ± 2.5 mm, $p < 0.001$).

In the group with reperfusion ventricular tachyarrhythmias, 1 patient developed ventricular fibrillation, 5 ventricular tachycardia, and 4 ventricular bigeminy. The rate of ventricular tachycardia ranged from 140 to 240 beats/min (mean 191 ± 56). Among the 6 patients

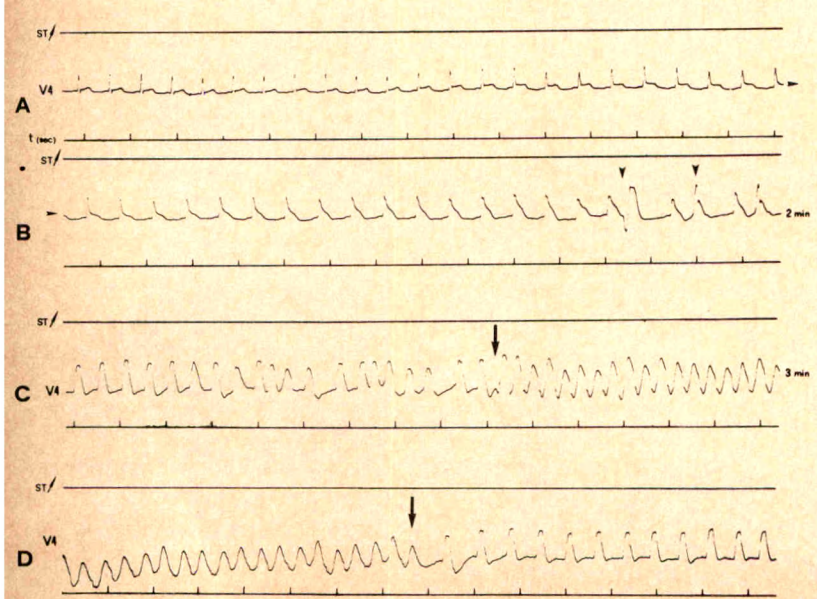

FIGURE 1. Occlusion ventricular arrhythmias in a patient with anterior S-T segment elevation. A bipolar lead similar to lead V_4 is monitored. At the onset of S-T segment elevation no ventricular arrhythmia is present (**strip A**). As the S-T segment elevation increases (**strip B; strips A and B** are continuous recordings), ventricular premature beats appear (**arrowheads**). After 2 minutes, at the time of maximal S-T segment elevation (**strip C**), ventricular tachycardia develops (**arrow**). When ventricular tachycardia reverts spontaneously to sinus rhythm (**strip D, arrow**), S-T segment elevation persists unchanged.

TABLE IV Comparison Between the Ischemic Episodes of Group I (Without Ventricular Tachyarrhythmias) and Group II (With Ventricular Tachyarrhythmias) Patients

	Group I	Group II	
		Occlusion VTA	Reperfusion VTA
Duration of ischemia (s)	216 ± 189	494 ± 319	801 ± 632*
Maximal S-T segment elevation (mm)	1.8 ± 1.0	5.2 ± 3.7*	6.3 ± 4.5*

* $p < 0.001$ compared with values in Group I.
All values are expressed as means ± standard deviation. VTA = ventricular tachyarrhythmias.

with ventricular arrhythmias during both occlusion and reperfusion phases, 3 showed ventricular tachycardia during both periods. The episodes associated with reperfusion arrhythmias in this group were significantly longer ($p < 0.001$) than those without arrhythmias in Group I patients (Table IV). In 6 of the 10 patients with reperfusion arrhythmias, the ischemic attacks lasted ≥10 minutes. Maximal S-T segment elevation was significantly greater ($p < 0.001$) in patients with reperfusion ventricular tachyarrhythmias than in Group I subjects (Table IV). In the 8 patients with reperfusion arrhythmias in whom ischemic episodes without rhythm disturbances were also present, the attacks associated with reperfusion arrhythmias showed a significantly longer duration (748 ± 568 versus 222 ± 109 seconds, $p < 0.05$) and a greater S-T segment elevation (7.1 ± 4.7 versus 3.5 ± 2.8 mm, difference not significant) than did those without arrhythmias.

Discussion

Incidence and clinical significance of ventricular arrhythmias in variant angina: The results of this study show that ventricular tachyarrhythmias are present in 1 or more ischemic attacks in 47% of patients with Prinzmetal's variant angina. Our findings are in agreement with those of Kerin et al,[5] who found sever dysrhythmias, including high-degree atrioventricula blocks, in 12 of 26 patients with variant angina, wherea other investigators[4] reported major rhythm distur bances, including severe bradyarrhythmias, in a smalle group of patients. The higher incidence of ventricula arrhythmias in our patients may be due to a differen patient population as well as to the fact that in the re ported study[4] the authors took into consideration onl patients with ventricular fibrillation or ventricula tachycardia; moreover, ventricular arrhythmias wer detected by central coronary care unit monitoring which consistently underestimates the frequency o ischemic attacks[17] and therefore, presumably, of ar rhythmias.

In the patients studied we did not find any significan correlation between the incidence of ventricular ar rhythmias and a series of clinical, electrocardiographic and angiographic parameters, including extent of cor onary artery lesions and baseline left ventricular func tion. Therefore clinical and angiographic features seen to be of limited value in recognizing patients with var iant angina who are at risk of developing life-threaten ing ventricular arrhythmias during the attacks. On th basis of our data, the severity of coronary artery diseas seems to play only a minor role in the pathogenesis o ventricular arrhythmias in variant angina, as previously suggested by other studies.[4,5] Recent experimenta findings[18] suggest that the risk of reperfusion ventric ular fibrillation may be greater in subjects without tha in those with coronary artery disease. In our study 3 o the 7 patients with reperfusion arrhythmias who un derwent coronary angiography showed normal or no critically diseased coronary arteries. Further studies i a larger population of patients with variant angina ar required to confirm the experimental results. Becaus in most of our patients left ventricular function wa normal or only mildly impaired, the influence of marked left ventricular depression on the frequency an severity of arrhythmias in variant angina is difficult t assess.

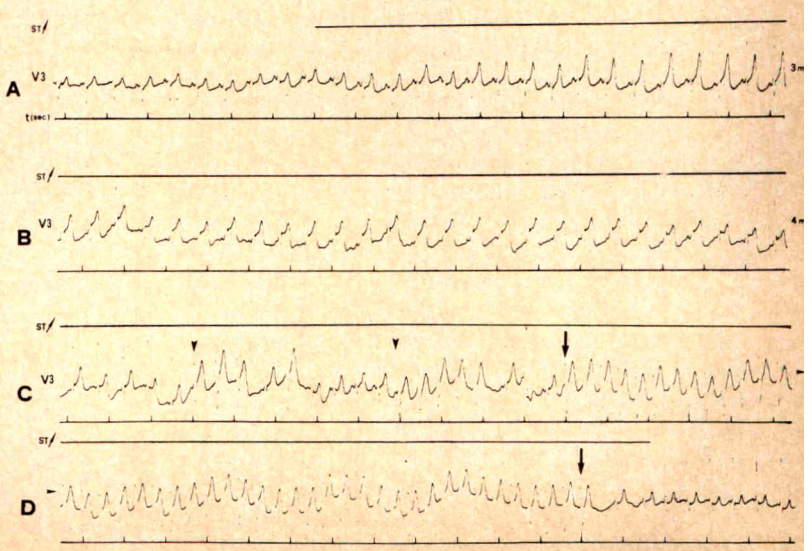

FIGURE 2. Reperfusion ventricular arrhythmias in a patient with anterior S-T segment elevation. A bipolar lead similar to lead V_3 is monitored. No ventricular arrhythmias occur at the onset of S-T segment elevation (**strip A**) and at the time of maximal S-T segment changes after 3 minutes of ischemia (**strip B**). When S-T segment elevation begins to decrease 4 minutes later (**strip C**), short runs of ventricular tachycardia (**arrowheads**) and then a sustained ventricular tachycardia (**arrow**) develop. Note that when the arrhythmia reverts spontaneously to sinus rhythm (**strip D, arrow**), the S-T segment has already returned to baseline.

Correlation of ventricular arrhythmias with severity of acute ischemia: In the present study as well as in previous reports,[5,19] the presence of ventricular arrhythmias during ischemic attacks was significantly correlated with the severity of ischemia, as estimated by the degree of S-T segment elevation: in fact, S-T segment elevation was significantly greater during the episodes associated with arrhythmias than during those without arrhythmias. Kerin et al[5] also showed that patients with ventricular arrhythmias during attacks of variant angina had S-T segment elevation of ≥4 mm, whereas in those without arrhythmias S-T segment elevation varied from 1.5 to 3 mm. Experimental studies suggest that, in the absence of intraventricular conduction disturbances, the degree of S-T segment elevation reflects the severity of ischemia[20]; moreover, S-T segment elevation correlates with the degree of tissue metabolic derangement,[21] reduction of coronary blood flow,[22] and alterations in intracellular potential.[23] Although experimental findings must be transferred cautiously to the clinical situation, the correlation between ventricular arrhythmias and degree of S-T segment elevation found in this study suggests that the severity of ischemia and its associated electrophysiologic alterations are critical in the genesis of ventricular arrhythmias in variant angina.

Relation of ventricular arrhythmias to occlusion and reperfusion phases: The experimental findings that both coronary artery occlusion and reperfusion are associated with malignant ventricular dysrhythmias, including ventricular fibrillation,[6–13] may be of clinical relevance, because in patients with variant angina coronary occlusive spasm and its subsequent release may reproduce the same sequence of events. The analysis of the relation of ventricular arrhythmias to the time course of S-T segment elevation in the patients studied showed that 23 of them had significant ventricular dysrhythmias close to or at the peak of S-T segment elevation, whereas in 10 patients ventricular arrhythmias occurred during resolution of the S-T segment alterations. Because there is experimental and clinical evidence that coronary artery occlusion is associated with S-T segment elevation[12,14,15] and reperfusion with return of S-T segment to baseline,[12,16] our findings suggest that in variant angina, ventricular arrhythmias may be triggered not only by coronary artery occlusion due to vasospasm, but also by reestablishment of coronary blood flow after relief of spasm.

In experimental animals the time course of ectopic activity is different after coronary artery occlusion compared with its release: Ventricular arrhythmias secondary to occlusion develop after a quiescent period of 1.5 to 2.5 minutes and reach a peak at 4 to 6 minutes[6,7,12]; by contrast, reperfusion dysrhythmias occur immediately after coronary artery release and are correlated with the duration of the antecedent period of coronary ligation.[9–12,24,25] The finding that in the patients studied occlusion arrhythmias developed at an average time of 3 minutes after the onset of ischemia is in keeping with the experimental results. Because the episodes associated with reperfusion arrhythmias were significantly longer than those without this type of arrhythmia, the duration of ischemia seems to be an important determining factor of reperfusion arrhythmias in human subjects also. Our results suggest that both occlusion and reperfusion arrhythmias are correlated with the degree of S-T segment elevation; thus the severity of myocardial ischemia seems to play a significant role in the pathogenesis of both types of dysrhythmia, although hemodynamic and nervous factors may significantly contribute to their development. Contrary to experimental studies showing a similar or even greater incidence of reperfusion arrhythmias than occlusion,[25,26] in the patients studied ventricular arrhythmias were more frequent during the occlusion phase than during reperfusion. This discrepancy could be due to the fact that in animals the incidence of reperfusion dysrhythmias increases as the period of preceding occlusion is prolonged from a few up to 30 minutes,[12,25] whereas the episodes of variant angina are usually of brief duration and so do not reproduce the metabolic and electrophysiologic alterations necessary for the development of arrhythmias during reperfusion.

Therapeutic implications: Patients with variant angina associated with severe ventricular arrhythmias have an early and late mortality higher than those without arrhythmias and are more likely to die suddenly.[4] Therefore they constitute a high-risk group in whom prevention of life-threatening arrhythmias is of utmost importance. In experimental studies various antiarrhythmic drugs used in the prevention of occlusion[27,28] or reperfusion[29–32] arrhythmias have led to equivocal and conflicting results. Because in variant angina coronary spasm is the underlying mechanism of acute ischemia leading to ventricular arrhythmias, a rational approach should aim at prevention of spasm rather than at treatment of arrhythmias once ischemia has developed. Calcium-antagonist drugs have been shown to be highly effective in the treatment of vasospastic angina[33–36]; moreover, experimental studies suggest that verapamil can prevent both occlusion and reperfusion ventricular tachyarrhythmias.[31,32,37] Therefore these drugs seem to be the treatment of choice in patients with vasospastic angina associated with ventricular tachyarrhythmias.

Long-Term Responses to Nifedipine in Patients With Coronary Spasm Who Have an Initial Favorable Response

JAMES A. HILL, MD, ROBERT L. FELDMAN, MD, C. RICHARD CONTI, MD, CAROL K. HILL, RN, and CARL J. PEPINE, MD

Twenty-six patients with angina and coronary spasm participated in a randomized crossover trial comparing nifedipine with isosorbide dinitrate. Eighteen patients had a short-term beneficial response to nifedipine, and 14 of these were followed up for an average period of 9.4 months. During follow-up study, nifedipine was the primary therapy in these 14 patients, but other drugs were added when clinically necessary to control angina. There was an overall 86% beneficial response rate (>50% decrease in angina frequency). However, 2 patients had a large increase (>10 times) and 4 patients had a slight increase (transient) in angina frequency over the long term compared with the short-term response. The other 8 patients had a similar angina frequency compared with the short-term response. Of the 12 patients with a good response (transient slight increase or no change), 8 (67%) required additional drug therapy to maintain angina control. Nifedipine was discontinued in 2, and the dose was decreased in 3 of the 14 patients because of adverse effects. Three patients had a marked increase in angina at 9, 14, and 3 months, requiring hospitalization; 1 patient had coronary bypass for symptom control. Thus, patients with coronary spasm selected because of a favorable short-term response to nifedipine were effectively treated over the long term with nifedipine; however, additional therapy was often needed to control symptoms. Adverse effects were common, but simple reduction of nifedipine dose usually diminished the unwanted effects of the drug.

Patients with rest angina and coronary spasm often receive long- and short-acting nitrates, calcium antagonists, and various combinations of these medications. Short-term efficacy of calcium antagonists has been demonstrated.[1–3] Studies also suggest beneficial long-term results.[4–6] These results occur, however, in patients receiving nifedipine as additive therapy to other antianginal agents. Numerous questions remain to determine optimal long-term management of patients with coronary spasm. Does a beneficial short-term response predict the same long-term response? Does therapy with nifedipine prevent cardiac events? Is nifedipine useful as single or primary therapy for long-term angina prophylaxis in patients with coronary spasm? Are additional medications, surgical procedures, or both necessary to continue a good therapeutic response? In view of these questions, a prospective investigation was conducted to determine the long-term effects of nifedipine therapy in a group of patients with coronary spasm who had a good initial response to the drug.

Methods

Patient selection: Twenty-six patients (22 men and 4 women) were entered into a double-blind randomized crossover trial comparing nifedipine and isosorbide dinitrate. All patients had angina, predominantly at rest, which was relieved by nitrates. All patients had cardiac catheterization studies performed before study entry. Our criteria for coronary spasm required demonstration of a major change in epicardial coronary diameter, either focal or diffuse, associated with objective evidence for transient myocardial ischemia reversed by nitrate.

All but 1 patient had angiographically documented coronary spasm. The latter patient had a normal coronary angiogram after sublingual nitrates were given. During angina, she had S-T elevation in electrocardiographic leads II, III, and aVF and varying degress of atrioventricular block, all of which were reversed by nitrates. No evidence of myocardial necrosis was found and left ventricular wall motion was normal.

TABLE I Long-Term Clinical Response

Patient	Nifedipine Dose (mg/day)	Duration of Therapy (mo)	Anginal Frequency: Long-Term Versus Previous Therapy	Anginal Frequency: Long-Term Versus Short-Term	Additional Antianginal Therapy
1	40	14	Increase	Increase	ISDN (40 mg)
2	80	8*	>50% decrease	NC	ISDN (80 mg), change to verapamil
3	40	19	>50% decrease	NC	NIF (40)
4	80	17	>50% decrease	NC	ISDN (40)
5	80†	9	NC	increase	Propranolol (360 mg), ISBN (120 mg), CABG
6	80†	3	>50% decrease	NC	. . .
7	40	16	ASX	NC	. . .
8	80†	7*	ASX	NC	ISDN (20 mg)
9	40	14	>50% decrease	NC	NIF (20 mg)
10	40	9	ASX	NC	. . .
11	80†	5	>50% decrease	Rare	. . .
12	120	5	>50% decrease	Rare	ISDN (40 mg)
13	80	3	>50% decrease	Rare	2% NTG ointment (4″)
14	120	3	>50% decrease	Rare	Topical NTG (10 mg), ISDN (120 mg)
Average	71	9.4	. . .	. . .	10 of 14

All patients had a >50% decrease in anginal frequency comparing short-term therapy and previous therapy.
* Drug discontinued because of adverse effects.
† Drug dose decreased by half because of adverse effects.
ASX = asymptomatic; CABG = coronary artery bypass graft; ISDN = isosorbide dinitrate; NC = no change; NIF = nifedipine; NTG = nitroglycerin.

These patients were entered into a short-term (12-week) trial which compared nifedipine with isosorbide dinitrate in a randomized double-blind crossover fashion. Details of this protocol and partial results of the short-term (12-week) trial have been reported previously.[1]

Of the 24 patients who completed the nifedipine phase of the random trial, 18 patients had a "beneficial" response defined as >50% decrease in angina frequency. Of these 18 patients, 14 continued to receive nifedipine and are the subjects of this report. The other 4 patients responded equally well to isosorbide dinitrate and continued to take the nitrate.

During follow-up study, the patients were evaluated by history, physical examination, electrocardiography, serum chemistry tests, and complete blood count, carried out at least every 2 months. Angina frequency and nitroglycerin consumption were tabulated from review of daily diaries.

Analysis of results: The lead-in phase of the short-term double-blind protocol was considered the baseline period for prior antianginal therapy and was used for all subsequent comparisons. The nifedipine phase of the short-term double-blind protocol was used to assess short-term responses. A >50% change in angina frequency was considered a beneficial response. The long-term responses were averaged monthly over the entire duration of follow-up study for each patient and compared with baseline and short-term response to nifedipine.

Results

Clinical data are summarized in Table I. The average length of follow-up study for the 14 patients was 9.4 months (range 3 to 19). All patients took nifedipine alone during the short-term portion of the study. Four patients (Patients 5, 6, 8, and 11) required a dose decrease from 80 to 40 mg/day because of adverse effects (fatigue in 1, edema in 1, headache in 1, and dizziness in 1). In 2 of these 4 patients (Patients 5 and 8), additional therapy was necessary to control angina. One of these 2 patients (Patient 8) eventually had the nifedipine discontinued because of adverse effects. One patient was asymptomatic with short-term therapy (Patient 11) but with dose reduction had rare (<1/week) angina; no additional therapy was instituted. The fourth patient (Patient 6) was poorly compliant and was changed to long-acting nitrates after 3 months. He was subsequently lost to follow-up study.

Two additional patients (Patients 4 and 10) had adverse effects during short-term treatment which resolved as therapy continued. In 1 of the remaining patients (Patient 2), nifedipine was discontinued because of adverse effects. This patient was given verapamil and responded satisfactorily. No other patient had a new adverse effect during long-term therapy.

No patients had abnormalities of serum chemistry values or complete blood count over the follow-up period.

Comparison of long-term therapy with previous antianginal therapy: Of the 14 patients, only 1 (Patient 1) had increased angina compared with previous therapy, which consisted of only sublingual nitrates. One other patient (Patient 5) had no change in angina frequency. Of the remaining 12 patients, 9 had a >50% decrease in anginal frequency and the other 3 were asymptomatic. This represents an 86% beneficial response with nifedipine compared with medication given before study.

Comparison of long-term with short-term therapy: Two patients (Patients 1 and 5) had a major increase (>10 times) in frequency of angina with long-term therapy. Four other patients (Patients 11, 12, 13 and 14) had a slight increase in symptoms compared with short-term results, but their angina frequency was <1/week and was considered a satisfactory response

Three patients (Patients 7, 8, and 10) remained asymptomatic with long-term therapy and the remaining 5 patients continued with a response similar to their short-term response.

Additional antianginal therapy: The 2 patients who had increased anginal frequency required additional therapy; 1 had long-acting nitrates (Patient 1), and the other had long-acting nitrates, propranolol, and finally coronary artery bypass surgery (Patient 5). Despite this additional treatment, both patients remained symptomatic. Six other patients (Patients 2, 4, 8, 12, 13, and 14) required long-acting nitrates to maintain a good therapeutic response. Two patients (Patients 3 and 9) had nifedipine increased by 40 and 20 mg day, respectively. Of the 12 patients who had a satisfactory beneficial long-term response, 8 (67%) required therapy in addition to their initial nifedipine dose to control angina.

Cardiac events: Cardiac events were defined as unstable angina, myocardial infarction, and sudden death. Only 3 patients (Patients 5, 9, and 14) had cardiac events while receiving long-term therapy. One patient of these 3 (Patient 14) had recurrent rest angina requiring hospitalization shortly after the short-term therapy trial. With addition of long-acting nitrates, her symptoms have been well controlled. Another patient (Patient 9) also had recurrent rest angina requiring hospitalization approximately 1 year after therapy was begun. The third patient (Patient 5) had rapidly increasing angina and underwent coronary artery bypass surgery. He had a perioperative myocardial infarction. It is not known whether coronary spasm was responsible for the myocardial infarction but subsequent catheterization revealed closure of all bypass grafts. No other patient experienced rest angina requiring hospitalization, myocardial infarction, or sudden death during the long-term follow-up period.

Discussion

In a group of patients with rest angina due to coronary spasm who had a good short-term response to nifedipine, the drug was effective in decreasing angina frequency in many over an average 9 month follow-up period. Eight of these 12 patients, however, required either a dose increase or additional antianginal therapy to maintain the good short-term response. Adverse effects necessitated discontinuation of therapy in 2 patients and decreasing the dose in 3 (total 36%). Coronary events (unstable angina requiring hospitalization) occurred in 3 patients.

Limitations: This study reports the long-term clinical responses of a group with an initial favorable response to nifedipine. There are several limitations in this study. First, there were no controls. Second, there was no uniform attempt to wean therapy or rechallenge with provocative agents such as ergonovine. Evaluation of spontaneous remission is thus impossible in all patients. A third limitation is the method used to average episodes of chest pain. Anginal frequency is variable in this group of patients. We arbitrarily averaged the number of episodes of pain per month for each patient over the follow-up period. Other methods may be used. Finally, there were no ambulatory electrocardiographic recordings made in the follow-up period. Our data, therefore, only represent symptomatic myocardial ischemia and are probably not a measure of total episodes of transient ischemia.

An additional problem that warrants consideration when evaluating long-term therapy of patients with coronary artery spasm is the spontaneous variability of symptoms.[7,8] Spontaneous attenuation of symptoms has been reported as high as 38%.[7] This is similar to the number in the present patient population who have remained in good clinical control with nifedipine alone. Seven of these patients have had their drug discontinued for various reasons. Only 1 has remained asymptomatic. Thus, it is not known whether current nifedipine therapy is needed to control symptoms.

Do short-term responses predict long-term responses? Only 2 patients had a major increase in anginal frequency comparing long- and short-term responses. Four other patients had a slight increase in symptoms which were controlled with long-acting nitrates or no additional therapy. These data are similar to other reports of the long-term efficacy of nifedipine.[4,5] Results from this study suggest that if patients demonstrate a good initial response, maintenance of decreased anginal frequency is possible in most patients but not necessarily with nifedipine alone.

Does nifedipine prevent cardiac events? Various investigators have reported a grave prognosis in patients with angina secondary to coronary spasm. MacAlpin et al[9] reported a 15% incidence of sudden death and 25% incidence of myocardial infarction within the first 3 months of symptoms. Recently, Miller et al[10] reported 114 patients with coronary spasm. They noted a 17% incidence of sudden death; no differences were found with respect to coronary artery disease or ventricular dysfunction. Recent data from Gerstenblith et al[11] in a group of patients with rest pain accompanied by electrocardiographic changes suggest nifedipine protects against some cardiac events, especially in those patients with S-T elevation. The current study group perhaps represents a low-risk group of patients for coronary events since anginal patterns were stable and angina was present, in many cases, for a prolonged period of time. Despite this, there was still a 21% incidence of cardiac events. Nifedipine does not seem to prevent their occurrence.

Nifedipine as primary therapy versus additional antianginal therapy: Although 12 patients had a good therapeutic response, 8 (67%) required additional antianginal therapy to maintain this response. The therapy of patients reported in this study differs from those previously reported in that nifedipine was the primary treatment. It was used as additive therapy in other trials.[4–6]

The patients in this report represent those who responded favorably to initial therapy with nifedipine alone. One might expect that long-term response to therapy would be favorable as these patients represent a select group. Despite this selection bias, 67% required

additional therapy to maintain good clinical response.

Adverse effects of the drug did limit long-term therapy in many patients (5 of 14) who responded satisfactorily during initial therapy. We have found a slightly higher incidence of adverse effects than that previously reported.[2,4–6] The explanation for this is unclear. Two patients with adverse effects responded well to a lower dose of nifedipine and a low dose of a long-acting nitrate. Combination therapy (nifedipine and nitrates) appears to be well tolerated by most patients.

All available published data suggest that nifedipine is effective therapy for angina in patients with coronary spasm. The current study confirms these results in a group of patients selected from a random trial who responded favorably to nifedipine and who were followed for approximately 1 year. However, adverse effects are relatively common and additional medications are often necessary to maintain a beneficial clinical response. Thus, it seems likely that individual drug dose adjustment and combination of nifedipine with other drugs known to be efficacious in patients with coronary artery spasm may be the logical and most effective way to treat patients with this condition.

Prognostic Value of Resting and Submaximal Exercise Radionuclide Ventriculography After Acute Myocardial Infarction in High-Risk Patients With Single and Multivessel Disease

PASCAL NICOD, MD, JAMES R. CORBETT, MD, BRIAN G. FIRTH, MD, DPhil, SAMUEL E. LEWIS, MD, ROBERT E. RUDE, MD, ROBERT HUXLEY, MD, and JAMES T. WILLERSON, MD

In patients who survive the acute phase of myocardial infarction, those with multivessel coronary artery disease generally have a worse prognosis than those with single-vessel disease. However, some patients with significant multivessel stenoses have a good prognosis, whereas some with a significant single-vessel stenosis have a poor prognosis. Thus, although definition of coronary anatomy may be helpful, it is a not a fail-safe prognosticator. In this retrospective analysis, the association of abnormalities at rest and during submaximal exercise testing with radionuclide ventriculography after acute myocardial infarction with major cardiac complications (death, recurrent infarction, severe angina or congestive heart failure) in the ensuing 6 months was assessed in patients with single and multivessel disease. Coronary angiography and submaximal exercise testing with radionuclide ventriculography were performed within 3 months of each other in 42 patients. Eleven of the 16 patients with single-vessel coronary stenosis had major cardiac complications. The subsequent course of these 16 patients was correctly predicted by left ventricular ejection fraction (LVEF) ≤0.40 in 8 patients, by LVEF <0.55 in 7 patients, by failure of LVEF to increase by 0.05 units in 13 patients, and by an increase in left ventricular end-systolic volume index (LVESVI) during exercise >5% above baseline in 11 patients. Of the 26 patients with multivessel coronary artery disease, 24 had major cardiac complications. The subsequent course of these 26 patients was correctly predicted in 13 by LVEF ≤0.40, in 20 by LVEF <0.55, in 25 by a failure of LVEF to increase by 0.05 units during exercise, and in 20 by an increase in LVESVI by >5% during exercise. Thus, submaximal exercise testing with radionuclide ventriculography may provide valuable prognostic information concerning the occurrence of major cardiac events after myocardial infarction not only in patients with multivessel disease, but also in those with single-vessel disease. Exercise-induced abnormalities of left ventricular function may have greater prognostic importance than the delineation of coronary arterial anatomy or the assessment of residual left ventricular function at rest.

After the acute phase of myocardial infarction (MI), certain patients remain at risk of developing serious late complications. Recent attempts to identify those patients at risk of late complications have utilized a variety of techniques: Some attempt to quantitate the amount of irreversibly damaged myocardium (for example, serial creatine kinase determinations and imaging with technetium stannous pyrophosphate or thallium), whereas others assess residual myocardial function (radionuclide ventriculography or echocardiography).[1–13] Still other techniques attempt to assess the amount of viable myocardium at risk of further damage. Specifically, submaximal exercise testing has been reported to be useful in the detection of patients at risk of developing further complications after infarction, and the simultaneous use of radionuclide techniques seems to improve both the sensitivity and specificity of exercise testing in detecting high-risk patients.[14–22] Alternatively, coronary angiography allows the recognition of patients with significant single or multivessel coronary arterial stenoses after MI; the presence of single-vessel disease is generally associated with a better

prognosis[23–26] because those with multivessel disease presumably have a greater amount of myocardium at risk of further damage. This retrospective analysis assesses the value of radionuclide ventriculography at rest and during submaximal exercise testing as predictors of major cardiac complications in patients with single or multivessel coronary artery disease.

Methods

Patient group: All patients admitted to the Coronary Care Unit at Parkland Memorial Hospital, Dallas, Texas with MI between August 1978 and August 1981 were considered for the present study. However, only those who underwent both submaximal exercise testing with radionuclide ventriculography and coronary angiography within 3 months of each other were included in this study. Submaximal exercise testing with radionuclide ventriculography was performed before hospital discharge in most patients after MI except for those with persistent angina at rest, severe congestive heart failure, or musculoskeletal disorders which would limit exercise, and those who would not consent to the procedure. Coronary angiography was performed only in certain clinical settings, namely, recurrent typical and atypical chest pain after MI in the hospital in 29 patients, infarct extension in 5 patients, congestive heart failure in 3 patients, a markedly abnormal exercise test at low work loads in 2 patients, refractory high-grade ventricular ectopy in 1 patient, and relatively young age (<40 years) in 2 patients. Twenty-one patients underwent catheterization during their initial admission for MI and 21 were readmitted subsequently for catheterization. Thus, the patients were a high-risk subgroup with a high incidence of early post-MI morbidity, and represent approximately 10 to 20% of the total number of patients with MI seen during this time period at Parkland Memorial Hospital.

The study group comprised 31 men and 11 women, aged 25 to 70 years (mean 50 ± 11). The diagnosis of MI was based on the presence of electrocardiographic, enzymatic (creatine kinase and creatine kinase-B isoenzymes), and scintigraphic (technetium-99m pyrophosphate) criteria.[27,28] MI was designated "transmural" when there were new Q waves ≥0.04 second in duration with associated ST-T wave changes, or a loss of R-wave height ≥50% in 2 or more leads of a conventional 12-lead electrocardiogram. The presence of typical ST-T wave changes and/or a loss of R-wave height <50% with associated enzymatic and scintigraphic changes compatible with MI was designated a "nontransmural" infarction.[29,30] The location of a transmural infarction was defined as either anterior (by the presence of typical changes in leads I, aVL, or V_1 to V_6) or inferior (by changes in leads II, III, or aVF).

Exercise testing protocol: All patients underwent supine bicycle exercise testing with radionuclide ventriculography 19 ± 9 (standard deviation) (range 12 to 52) days after infarction while taking their usual medications. The Frank lead system was used for continuous monitoring of the electrocardiographic response to exercise.[31] Cuff-determined blood pressures were also recorded at rest and near the completion of each work load. Exercise commenced at 150 or 300 kilopond-meters (kpm)/min and increased by 150 to 300 kpm/min at each subsequent exercise level depending on age, physical condition, and performance at the previous work load. The patients exercised for 4 minutes at incremental work loads until 1 of the following endpoints was reached: (1) a heart rate of 130 beats/min; (2) complex ventricular arrhythmias; (3) progressive chest discomfort compatible with angina pectoris; (4) S-T segment depression ≥0.2 mV (0.08 second after the J point) compared with the resting electrocardiogram; (5) a decrease in blood pressure during exercise; (6) exhaustion or marked dyspnea. Electrocardiographic monitoring was continued for 10 minutes after the completion of exercise.[32,33]

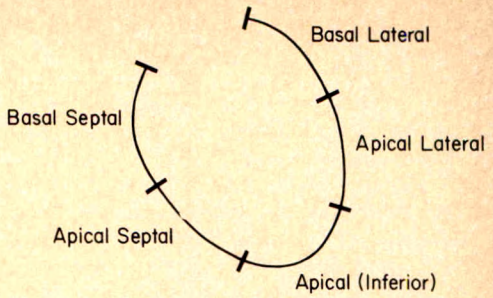

FIGURE 1. Wall segment identification and analysis. The left ventricl was divided into 5 segments of approximately equal length. Segmenta wall motion abnormalities before and during exercise were graded a follows: 4 = normokinesia; 3 = mild hypokinesia; 2 = severe hypok nesia; 1 = akinesia; and 0 = dyskinesia.

Radionuclide ventriculography: Multigated equilibriur blood pool imaging was performed using an in vivo techniqu of labeling red blood cells with 20 to 30 mCi of technetium 99m sodium pertechnetate.[20] Images were acquired using parallel-hole collimator and a gamma scintillation camer (Technicare Series 120, Solon, Ohio). Data acquisition wa performed in a modified 15° to 60° left anterior oblique pro jection with a 0° to 20° caudal tilt adjusted to provide the bes definition of the interventricular septum. All images wer acquired at a temporal resolution of 32 frames per cardia cycle for a preselected time interval of 3 minutes. Data ac quisition was commenced at each work load after 1 minute c exercise.[14] Left ventricular ejection fraction (LVEF) wa calculated using a standard count-related technique, afte background subtraction.[34] Left ventricular volumes wer calculated using a nongeometric technique recently describe from our laboratory.[34,35] Left ventricular segmental wal motion was analyzed subjectively from a cinematic display b 2 experienced observers. The left ventricle was divided int 5 segments as shown in Figure 1. Each segment was grade according to the following scale: 0 = dyskinesia, 1 = akinesia 2 = severe hypokinesia, 3 = mild hypokinesia, and 4 = nor mokinesia. The scores for all segments were summed both a rest and at each exercise level and expressed as a percentag of the maximal possible score. New wall motion abnormalitie during exercise were categorized according to their locatio as occurring in a previously abnormal area or in an adjacen or remote area by comparison with the ventriculogram at res Two levels of abnormal left ventricular function at rest wer defined, namely, LVEF ≤0.40 and <0.55, respectively. A abnormal response to exercise was defined as a failure t achieve an increase in LVEF of 0.05 units, or an increase c end-systolic volume index (LVESVI) by ≥5%.

Coronary angiography: All patients underwent left-side cardiac catheterization and coronary angiography in multipl projections 36 ± 23 days after their MI. The coronary angio grams were interpreted by at least 2 experienced observer who had no knowledge of the clinical course or the result c the exercise test with radionuclide ventriculography. A lesio was designated as significant when it involved ≥70% of th luminal diameter of the vessel.

Follow-up: Each patient was followed up closely in th cardiology clinic for 8 ± 6 months. Patients were classified int 2 groups based on the presence or absence of "major cardia complications" during the period of follow-up, including: (1 sudden death; (2) death due to cardiac causes; (3) recurren

MI; (4) class III or IV angina pectoris; and (5) congestive heart failure resistant to therapy. The remaining patients were either asymptomatic or had mild angina or congestive heart failure that responded to medical therapy.

Statistical analysis: The patients described in this study represent a high-risk subgroup of patients who underwent submaximal exercise testing with radionuclide ventriculography and coronary angiography after acute MI and who had a higher incidence of late complications than would be anticipated in an unselected group after MI. Therefore, we have stated our findings in specific rather than general terms and have reported the frequency with which each of the radionuclide-determined variables predicted the correct outcome in our group of patients with single and multivessel coronary artery disease.

Data are expressed as mean ± 1 standard deviation. Comparison of proportions in 2 groups was performed using an adjusted chi-square analysis.[36] A comparison of means was performed, where appropriate, using Student's *t* test modified for unequal variances.[36] A 2-tailed p value ≤0.05 was considered significant.

Results

Clinical features: The age and sex of the patients, as well as the site and extent of infarction, the presence or absence of a previously documented infarction, or systemic arterial hypertension are listed in Table I. Patients with significant single-vessel coronary arterial stenoses tended to have a lower incidence of previous MI, but this difference was not statistically significant (p = 0.09).

Coronary angiography: Sixteen patients had angiographic evidence of single-vessel coronary arterial stenosis, whereas 26 had significant double- or triple-vessel disease. The vessels involved, as well as the site of the infarction, are listed in Tables II and III. Vessels with noncritical narrowings are also listed in these tables.

Rest and exercise radionuclide ventriculography: The results of the rest and exercise radionuclide ventriculographic studies for individual patients are shown in Tables I to III and in Figures 2 and 3. Only 3 patients with single-vessel disease had LVEF ≤0.40, compared with 13 of 26 with multivessel disease (p = 0.09). The mean LVEFs in patients with single and multivessel disease were 0.55 ± 0.17 and 0.44 ± 0.14, respectively (p <0.03). The LVEF response to exercise was more normal in patients with single-vessel disease (+0.02 ± 0.10 versus −0.06 ± 0.06, p <0.01) (Table I). LVESVI at rest was smaller in patients with single-vessel disease than in those with multivessel disease (42 ± 25 versus 63 ± 28 ml/m^2, p <0.02) and the mean increase in LVESVI during exercise in patients with single-vessel disease was smaller than in those with multivessel disease (+2 ± 9 versus +12 ± 15 ml/m^2, p = 0.01).

Follow-up and prognostic value of rest and exercise radionuclide ventriculography in relation to coronary anatomy: The results of clinical follow-up in each patient are listed in Tables II and III. Most of the patients with 2- or 3-vessel disease had a complicated course after infarction, whereas patients with single-vessel disease had a variable course.

In the 16 patients with single-vessel coronary artery disease, the subsequent course was correctly predicted in 13 by LVEF response to exercise, in 8 by resting LVEF ≤0.40, and in 7 by resting LVEF <0.55 (p = 0.07

TABLE I Clinical Characteristics and Results of Exercise Radionuclide Ventriculography in Patients With Single and Multivessel Coronary Artery Disease

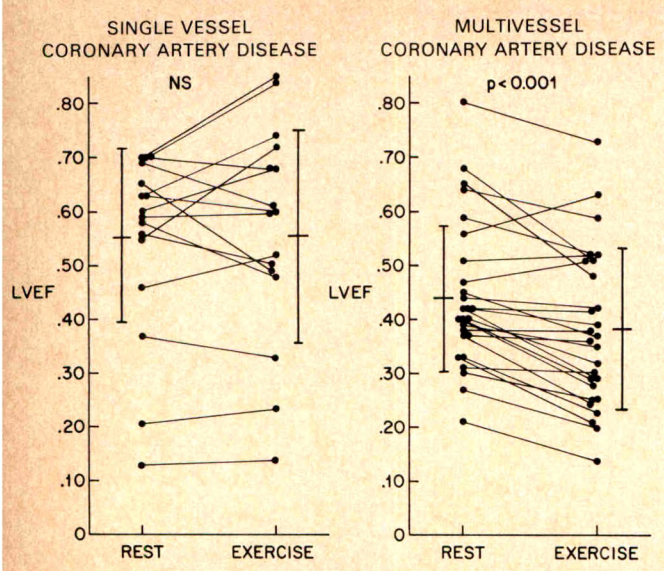

FIGURE 2. Response of the left ventricular ejection fraction (LVEF) to exercise in patients with single or multivessel coronary artery disease after acute myocardial infarction. In the group with single-vessel disease, LVEF changed from 0.55 ± 0.17 at rest to 0.56 ± 0.20 at peak exercise (difference not significant [NS]). The group with multivessel disease showed a decrease in LVEF from 0.44 ± 0.14 at rest to 0.38 ± 0.15 at peak exercise ($p < 0.001$).

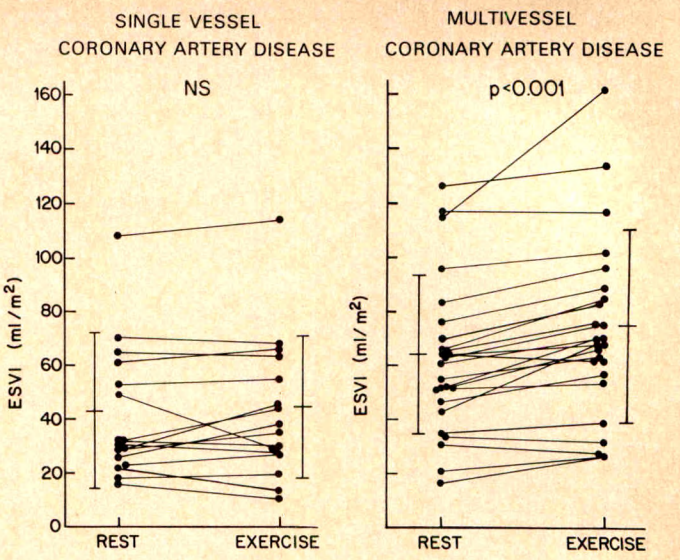

FIGURE 3. Response of the left ventricular end-systolic volume index (ESVI) in patients with single (**left panel**) or multivessel (**right panel**) coronary artery disease. In the group with single-vessel disease, left ventricular ESVI changed from 42 ± 25 ml/m² at rest to 43 ± 26 at peak exercise (difference not significant [NS]). In those with multivessel disease, left ventricular ESVI increased from 63 ± 28 ml/m² at rest to 76 ± 37 at peak exercise ($p < 0.001$).

compared with the prognostic value of the LVEF response to exercise). An increase in LVESVI by >5% in response to exercise predicted the correct outcome in 11 patients (difference not significant compared with the prognostic value of the LVEF response). In the 26 patients with multivessel coronary artery disease, the subsequent course was correctly predicted in 25 by LVEF response to exercise, in 13 by resting LVEF ≤0.40 ($p < 0.001$ compared with LVEF response to exercise), in 20 by resting LVEF <0.55, and in 20 by an increase in LVESVI by >5% in response to exercise ($p = 0.10$ compared with LVEF response to exercise). Thus, both in patients with single and in those with multivessel coronary artery disease, the LVEF response to exercise may provide more prognostic information than mere knowledge of resting LVEF.

Segmental wall motion analysis: In response to exercise, patients with 2- or 3-vessel disease tended to have more wall motion abnormalities at sites adjacent to or remote from resting wall motion abnormalities than patients with single-vessel disease (Table I). However, there was considerable overlap between the 2 groups so that segmental wall motion abnormalities during exercise could not be used to differentiate patients with single and multivessel disease.

Discussion

Techniques aimed at assessing residual cardiac function after MI have helped define groups of patients at high or low risk after this event. However, some patients may have well-preserved myocardial function at rest and still have major complications. Such patients probably have regions of viable myocardium at risk of further ischemic damage. Exercise testing, with or without radionuclide techniques, and coronary angiography have both been proposed as means of identifying such patients.[14–22] We previously reported the prognostic value of a wide variety of patient-related variables after acute MI in an unselected group of patients using stepwise discriminant analysis.[14] Although the value of submaximal exercise testing with radionuclide ventriculography was demonstrated in this study, coronary angiographic information was not available for this unselected group of patients. Therefore, the relation between radionuclide determined variables and coronary angiographic findings after MI, and the relation of both these variables to the subsequent course, could not be assessed.

In our selected group of patients, those with multivessel disease had a poor prognosis after MI, as has been reported by other investigators.[23–26] These patients had an almost uniformly abnormal response to exercise. Those with single-vessel coronary artery disease generally had a better prognosis; however, some had subsequent major cardiac events. Although depressed resting left ventricular function, when present, was generally associated with a poor outcome, it was not a sensitive predictor of subsequent cardiac events. Conversely, functional alterations during exercise detected most of the patients with a complicated clinical course irrespective of whether they had single or multivessel disease. Therefore, functional alterations during exercise after MI may be a better prognostic indicator than mere knowledge of coronary anatomy or residual left ventricular function.

Possible reasons for exercise-induced abnormalities of left ventricular function: In patients with multivessel disease, an abnormal response to exercise

after MI can be explained by ischemic dysfunction of remote areas of myocardium that are supplied by diseased coronary arteries and are at risk of further damage.[37] The explanation for the abnormal response to exercise in certain patients with single-vessel disease is less readily apparent, but may be due to several factors: (1) the MI may not have involved all the territory supplied by the diseased artery—a "border zone" of myocardium supplied by collateral vessels remains, which may become ischemic during increased myocardial oxygen demand, such as occurs during exercise; (2) the infarcted myocardium may cause a zone of akinesia or dyskinesia around which wall tension is increased, producing increased myocardial oxygen demand and diminished supply; (3) the extent of the disease process may be underestimated in the uninvolved arteries due to the diffuseness of the atherosclerotic process; and (4) coronary artery spasm may develop in uninvolved arteries during exercise.

Aneurysm formation and increased wall tension in the border zone of the infarct is an unlikely explanation because only 3 of 9 patients with single-vessel disease and an abnormal exercise test had an akinetic or dyskinetic area. Underestimation of the atherosclerotic process in uninvolved arteries is a possibility. Although coronary arterial spasm has been described during exercise,[38] it is probably uncommon. We believe that after MI, there may be a border zone of myocardium supplied mostly by collateral vessels, or residual flow, which is susceptible to further ischemia during periods of increased myocardial oxygen demand. However, this hypothesis awaits confirmation. Patients with single-vessel disease tended to have wall motion abnormalities during exercise confined to the site of MI, whereas patients with multivessel disease developed wall motion abnormalities at more distant sites.

Clinical implications and limitations of the study: The major limitation of this study is that it is a retrospective analysis of a select group of patients who underwent cardiac catheterization after MI, frequently because of a complicated clinical course. Therefore, it is not surprising to find a higher incidence of complications in our patients as a whole, and in particular in the subgroup with single-vessel disease, than has generally been reported in less selected groups of patients.[23–26] However, our data suggest that radionuclide ventriculography with submaximal exercise testing after MI provides valuable prognostic information not provided by mere delineation of coronary arterial anatomy or resting left ventricular function. A prospective study of a representative group of patients with single and multivessel coronary artery disease who undergo cardiac catheterization as well as rest and exercise radionuclide ventriculography will be necessary to confirm our findings.

Finally, our data suggest that every attempt should be made to protect those patients with exercise-induced deterioration in left ventricular function from further cardiac complications. Whether some or all of these patients with single- or multivessel coronary artery disease will benefit from revascularization or intensive medical therapy remains to be determined.

Free Your Angina Patient...
from some constraints of
beta-blocker therapy

Calan® TABLETS
80 mg and 120 mg
(verapamil HCl)

A Freer Life-style For Your Angina Patients

Unsurpassed by propranolol in the treatment of angina

- The efficacy of Calan was unsurpassed by that of propranolol in well-controlled comparative studies involving patients with chronic stable angina.[1-4]
- Calan is very effective in unstable[5] and variant angina,[6] where spasm factors may preclude the use of propranolol.[7]

Low incidence of unwanted effects

- Serious adverse reactions are rare with Calan at recommended doses; the single most common unwanted effect is constipation (6.3%). The therapy continuation rate was 94.5% in clinical studies.[8]
- Unlike beta-blockers, Calan rarely causes extreme fatigue or mental depression.

Benefits even for patients who can't take propranolol

- Calan, unlike propranolol, can be used without added caution in angina patients who also have asthma, chronic obstructive pulmonary disease (COPD), or diabetes.

The only non-nitrate indicated for initial therapy for all types of angina

TABLETS
80 mg and 120 mg

A Freer Life-style For Your Angina Patients

▪ Efficacy unsurpassed by propranolol

Calan is effective and, unlike propranolol, is indicated as initial therapy both for stable effort angina and for vasospastic angina.

▪ Therapeutic considerations similar to propranolol

Calan and propranolol have similar cardiovascular contraindications and many of the same cardiovascular adverse reactions (e.g., hypotension, reduction of myocardial contractility, and intensification of AV block).[8,9]

▪ An easy-to-titrate dosage schedule

Initial dosage: 80 mg t.i.d.

Calan 80 · Calan 80 · Calan 80

Titrate to optimal response: usually 120 mg t.i.d. or q.i.d.

Calan 120 · Calan 120 · Calan 120 · Calan 120

Calan® (verapamil HCl) TABLETS
80 mg and 120 mg

Contraindications: Severe left ventricular dysfunction (see *Warnings*), hypotension (systolic pressure<90 mm Hg) or cardiogenic shock, sick sinus syndrome (if no pacemaker is present), 2nd- or 3rd-degree AV block. **Warnings:** Verapamil should be avoided in patients with severe left ventricular dysfunction (eg, ejection fraction<30%) or moderate to severe symptoms of cardiac failure. Control milder heart failure with optimum digitalization and/or diuretics before Calan is used. Calan may occasionally produce hypotension usually asymptomatic, orthostatic, mild, and controlled by decrease in Calan dose. Occasional elevations of liver enzymes have been reported; patients receiving verapamil should have liver enzyme levels monitored periodically. Patients with atrial flutter/fibrillation and an accessory AV pathway (eg, WPW or LGL syndromes) may develop a very rapid ventricular response after receiving verapamil (or digitalis). Treatment is usually D.C.-cardioversion. AV block may occur (3rd-degree, 0.8%). Development of marked 1st-degree block or progression to 2nd- or 3rd-degree block requires reduction in dosage or, rarely, discontinuation and institution of appropriate therapy. Sinus bradycardia, 2nd-degree AV block, sinus arrest, pulmonary edema and/or severe hypotension were seen in some critically ill patients with hypertrophic cardiomyopathy who were treated with verapamil. **Precautions:** Verapamil should be given cautiously to patients with impaired hepatic function (in severe dysfunction use about 30% of the normal dose) or impaired renal function and patients should be monitored for abnormal prolongation of the PR interval or other signs of overdosage. Studies in a small number of patients suggest that concomitant use of Calan and beta-blockers may be beneficial in patients with chronic stable angina. Combined therapy can also have adverse effects on cardiac function. Therefore, until further studies are completed, verapamil should be used alone if possible. If combined therapy is used, patients should be monitored closely. Combined therapy with verapamil and propranolol should usually be avoided in patients with AV conduction abnormalities and/or depressed left ventricular function or in patients who have also recently received methyldopa. Chronic verapamil treatment increases serum digoxin levels by 50% to 70% during the first week of therapy, which can result in digitalis toxicity. The digoxin dose should be reduced when verapamil is given, and the patient carefully monitored. Verapamil may have an additive hypotensive effect in patients receiving blood-pressure-lowering agents. Disopyramide should not be given within 48 hours before or 24 hours after verapamil administration. Until further data are obtained, combined verapamil and quinidine therapy in patients with hypertrophic cardiomyopathy should probably be avoided, since significant hypotension may result. Adequate animal carcinogenicity studies have not been performed. One study in rats did not suggest a tumorigenic potential, and verapamil was not mutagenic in the Ames test. Pregnancy Category C. There are no adequate and well-controlled studies in pregnant women. This drug should be used during pregnancy, labor, and delivery only if clearly needed. It is not known whether verapamil is excreted in breast milk; therefore, nursing should be discontinued during verapamil use. **Adverse Reactions:** Hypotension (2.9%), peripheral edema (1.7%), AV block: 3rd-degree (0.8%), bradycardia: HR<50/min (1.1%), CHF or pulmonary edema (0.9%), dizziness (3.6%), headache (1.8%), fatigue (1.1%), constipation (6.3%), nausea (1.6%). The following reactions, reported in less than 0.5% of patients, occurred under circumstances where a causal relationship is not certain: confusion, paresthesia, insomnia, somnolence, equilibrium disorders, blurred vision, syncope, muscle cramps, shakiness, claudication, hair loss, macular eruptions, and spotty menstruation. Overall continuation rate was 94.5% in 1,166 patients. **How Supplied:** Calan (verapamil HCl) is supplied in 80-mg and 120-mg sugar-coated tablets.

Evaluation of a QRS Scoring System in Acute Myocardial Infarction: Relation to Infarct Size, Early Stage Left Ventricular Ejection Fraction, and Exercise Performance

YOSHIHIKO SEINO, MD, HOWARD M. STANILOFF, MD, WILLIAM E. SHELL, MD, DAVID MICKLE, RCPT, PREDIMAN K. SHAH, MD, and JOHN K. VYDEN, MB

Recent studies suggest that the QRS scoring system (QRSs) using observations of Q- and R-wave duration and R/Q and R/S amplitude ratios in the standard electrocardiogram (ECG) is useful in estimating left ventricular function after acute myocardial infarction (AMI).

The correlation of QRSs with infarct size determined by serum creatine kinase MB changes and early stage left ventricular ejection fraction (LVEF) determined by multiple gated equilibrium cardiac blood pool scintigraphy was studied in 32 patients with AMI using ECGs taken 3 and 7 days after onset. The relation of QRSs to exercise performance was also examined in 45 other patients who underwent heart rate limited low level exercise test (LLET) soon after AMI (12.3 ± 5.6 days, mean ± standard deviation).

The QRSs of 7 days after onset significantly correlated with both infarct size and LVEF; infarct size (CK·g·Eq) = 5.24 QRSs + 8.50 ($r = 0.72$, $p < 0.001$), LVEF (%) = −2.16 QRSs + 59.58 ($r = -0.71$, $p < 0.001$).

Patients with exercise tolerance of <6 minutes had significantly higher QRSs than patients wit exercise tolerance of 6 to 12 minutes or >12 mi utes (9.0 ± 3.3 versus 4.5 ± 2.4 and 3.6 ± 2.2, <0.001, respectively). All patients with QRSs < (24 of 45 patients) achieved exercise tolerance >5 minutes, whereas all patients who could n exercise for >5 minutes (10 of 45 patients) ha QRSs >5.

The relation between QRSs and the reasons fo termination of LLET showed that patients with fa tigue or dyspnea, or both, had significantly highe QRSs (8.7 ± 4.6) than those in target heart rate (5. ± 2.2, $p < 0.05$) and those in completed protoc (3.0 ± 1.7, $p < 0.01$), whereas patients with ches pain had intermediate QRSs (5.3 ± 2.7). The QRS was significantly higher in patients with S-T change during LLET (8.2 ± 4.5 versus 4.7 ± 2.8, <0.05).

These data suggest that QRSs will be clinicall useful not only as a variable correlating with infarc size and LVEF but also as an aid in early identif cation of exercise performance soon after AMI.

Primary loss of functioning myocardium is the most important cause of pump failure, and the amount of residual functioning myocardium is the major determinant of cardiac function in acute myocardial infarc tion (AMI).[1,2] Therefore, the evaluation of infarct siz and residual cardiac function has become essential i the treatment of patients with AMI.

To assess cardiac function, hemodynamic variable are monitored with a Swan-Ganz thermodilutio catheter or cardiac nuclear ventriculography is useful.[3] To assess residual cardiac function, the low level exe cise test is performed safely soon after AMI.[6–8]

Estimation of infarct size has been attempted b techniques such as analysis of changes in serum creatin kinase (CK),[9–11] nuclear ventriculography,[12–14] an

analysis of electrocardiographic changes.[15–17] As the first 2 techniques have limitations in cost and availability, further investigations can be expected for possible establishment of the electrocardiographic method.

Recent studies by Palmeri et al[18] and Wagner et al[19] suggest the clinical usefulness of their QRS scoring system using standard 12-lead electrocardiograms to assess left ventricular function in patients with previous myocardial infarction.

The present study was performed to investigate the clinical values of their QRS scoring system (QRSs) in the early stage of AMI in terms of (1) how QRSs actually correlates with enzymatically estimated infarct size and early stage left ventricular ejection fraction (LVEF) determined by cardiac blood pool scintigraphy, and (2) relation to exercise test results soon after AMI.

Methods

Patients: This study consisted of 2 groups of patients, both having a first transmural AMI; the correlation studies investigated 42 patients (8 women, 34 men, aged 27 to 83 years, average 61.8) to determine the correlation between QRS score, enzymatically estimated infarct size, and early stage LVEF. The exercise performance study investigated 45 patients (11 women, 34 men, aged 30 to 86 years, average 60.9) to study the relation between QRS score and exercise performance soon after AMI.

TABLE I QRS Scoring System[18,19]

Lead	Q-Wave Duration (ms)		R-Wave Duration (ms)	Amplitude Ratios	Points	Maximum
I	≥30				1	
				R/Q ≤1	1	2
II	≥40				2	
	≥30				1	2
aV_L	≥30				1	
				R/Q ≤1	1	2
aV_F	≥50				3	
	≥40		•		2	
	≥30				1	
				R/Q ≤1	2	
				R/Q ≤2	1	5
V_1	Any				1	
			≥50		2	
			≥40		1	
			. . .	R/S ≥1	1	4
V_2	Any	or	≤20		1	
			≥60		2	
			≥50		1	
				R/S ≥1.5	1	4
V_3	Any	or	≤30		1	1
V_4	≥20				1	
				R/Q or R/S ≤0.5	2	
				R/Q or R/S ≤1.5	1	3
V_5	≥30				1	
				R/Q or R/S ≤1	2	
				R/Q or R/S ≤3	1	3
V_6	≥30				1	
				R/Q or R/S ≤1	2	
				R/O or R/S ≤3	1	3

The diagnosis of transmural AMI was based on the presence of all of the following criteria: (1) prolonged chest pain beyond 30 minutes, (2) development of a new Q wave with S-T elevation, and (3) characteristic elevation of serum CK including MB isoenzyme fraction, glutamic oxaloacetic transaminase, and lactic dehydrogenase. Patients with a history or electrocardiographic evidence of previous myocardial infarction or significant valvular disease were excluded from this study. Also, patients undergoing intraaortic balloon pumping, cardiac pacing, or intracoronary thrombolysis were excluded.

The anterior or inferior location of AMI was characterized according to established electrocardiographic criteria.[20] Of 42 patients in the correlation study, 27 had anterior and 15 had inferior MI, whereas in 45 patients in the exercise performance study, 18 had anterior and 27 had inferior MI.

QRS scoring system[18,19]: For this study, electrocardiograms taken 3 and 7 days after the onset of symptoms were used for QRS scoring in the correlation study. In the exercise performance study, resting control electrocardiograms taken at low level exercise testing were used for scoring.

Standard 12-lead electrocardiograms were scored according to the QRS scoring system based on the accumulation of a point score designed to estimate infarct size, as described by Palmeri et al[18] and Wagner et al.[19] The criteria for scoring are applied to each of 10 leads (I, II, aVL, aVF, and V_1 to V_6) and are derived from Q- and R-wave duration and R/Q and R/S amplitude ratios (Table I). All electrocardiograms were scored by 2 cardiologists independently without knowledge of the tracing's origin and of the results of other studies. If the 2 cardiologists scored differently, the third cardiologist determined the final score. If right or left bundle branch block, nonspecific intraventricular conduction delay (QRS ≥110 ms), or left anterior fascicular block (QRS axis ≤ −60°) was present on the electrocardiogram, the patient was excluded from QRS scoring.[18,19]

Measurement of infarct size by CK-MB: Serum CK-MB levels were determined by column chromatography as previously described by Shell et al.[21,22] Infarct size was computed by analysis of serum CK-MB changes using the formula of Sobel,[9] Shell[10] and their associates.

Measurements of early stage LVEF[5,23]: Multiple gated equillibrium cardiac blood pool scintigraphy in the 45° left anterior oblique and anterior views was performed within 48 hours of the onset of symptoms, after injection of 20 to 25 mCi of in vitro labeled technetium-99m autologous red blood cells, using a mobile gamma camera (Ohio Nuclear 420) equipped with a low-energy all-purpose collimater and a mobile computer (Medical Data System). No patients were receiving digitalis, propanolol, vasodilators, or sympathomimetic agents at the time of the scintigraphic study. LVEF was determined semiautomatically from the background-corrected left ventricular activity-time course. LVEF = (end-diastolic counts − end-systolic counts)/end-diastolic counts.

Low level exercise test soon after AMI: The low level exercise test was performed before hospital discharge. Average time from AMI to exercise test was 12.3 ± 5.6 days (mean ± standard deviation). This study excluded patients with coronary bypass surgery or evidence of left heart failure (lung rales or gallop sounds). Each patient had a 12-lead electrocardiogram at rest as a control before starting the treadmill test. A CM_5 lead was placed and monitored continuously throughout the exercise test and for at least 5 minutes thereafter or until the electrocardiogram returned to baseline. Recorded electrocardiogram strips, heart rate, and blood pressure were taken each minute. Patients were exercised on a treadmill according to a modified Bruce protocol.[24,25] Cri-

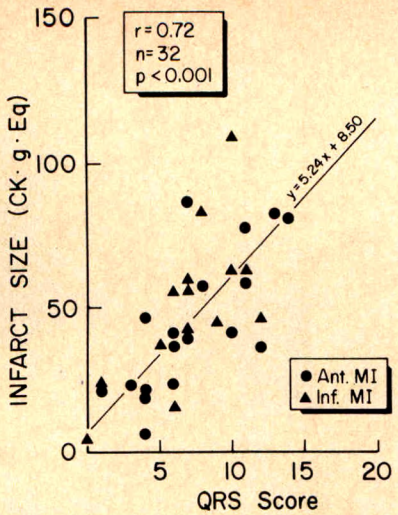

FIGURE 1. Correlation between QRS score and enzymatically estimated infarct size. Ant. MI = anterior myocardial infarction; Inf. MI = inferior myocardial infarction.

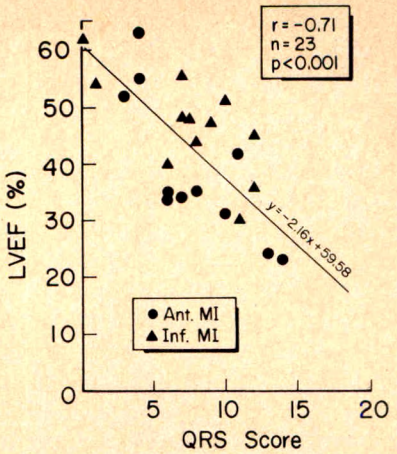

FIGURE 2. Correlation between QRS score and early stage left ventricular ejection fraction (LVEF). Abbreviations as in Figure 1.

teria for termination of the test were the development of chest pain, excessive fatigue or dyspnea, heart rate >120 beats/min (heart rate >100 beats/min in patients taking beta-blocking drugs), warning arrhythmias (premature ventricular contractions >6/min, R on T phenomenon), or METs >7 (equal to completion of the protocol).

Statistical analysis: All data are expressed as mean ± standard deviation. Pearson correlation coefficients between QRS score and enzymatically estimated infarct size and LVEF were obtained by simple linear regression analysis. The significance of difference in the QRS score between subgroups in exercise performance study was assessed using Kruskal-Wallis 1-way analysis of variance and Fisher's least significance difference. The QRS score in patients with and without exercise S-T changes was compared using the Mann-Whitney test.

Results

QRS score versus infarct size and early stage LVEF: Ten of 42 patients were excluded from QRS scoring because of right bundle branch block in 7, left bundle branch block in 1, and left anterior fascicular block in 2.

The QRS score 3 days after the onset of symptoms did not show any significant correlation with early stage LVEF nor enzymatically estimated infarct size. The QRS score 7 days after onset showed significant correlation with both early stage LVEF and infarct size.

The correlation between QRS score and enzymatically estimated infarct size is shown in Figure 1. Linear regression analysis demonstrated a significant correlation between QRS score and infarct size ($r = 0.72$, $n = 32$, $p < 0.001$). The equation for predicting infarct size from QRS score was: infarct size (CK·g·Eq) = 5.24 QRS score + 8.50.

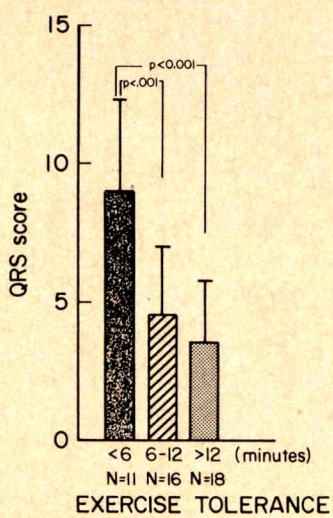

FIGURE 3. Relation between exercise tolerance and QRS score.

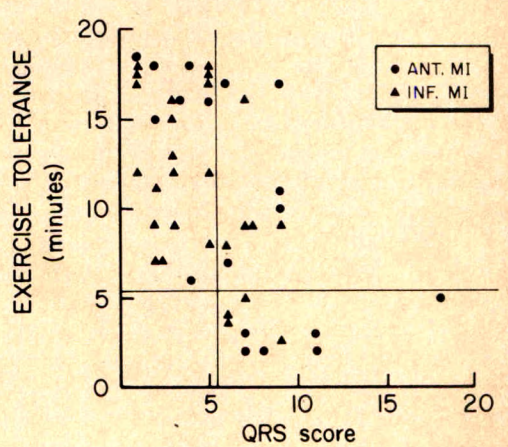

FIGURE 4. Relation between exercise tolerance and QRS score. Abbreviations as in Figure 1.

Similarly, the correlation between QRS score and early stage LVEF is shown in Figure 2. There was a significant inverse correlation between QRS score and LVEF ($r = -0.71$, $n = 23$, $p < 0.001$), with LVEF (%) = -2.16 QRS score + 59.58.

QRS score versus exercise performance: Of the 42 patients, 6 completed the protocol (achieved METs >7), 39 patients could not complete the protocol because of target heart rate (22 patients), chest pain (9 patients), excessive fatigue or dyspnea, or both (7 patients), and frequent premature ventricular contractions (1 patient). Six patients showed S-T depression >1.0 mm and 1 patient had S-T elevation >1 mm during low level exercise tests.

Figure 3 shows the relation between exercise tolerance and QRS score in these patients. Patients with exercise tolerance <6 minutes had a significantly higher QRS score compared with those with exercise tolerance 6 to 12 minutes or more (9.0 ± 3.3 versus 4.5 ± 2.4 and 3.6 ± 2.2, $p < 0.001$, respectively). Figure 4 also shows that all patients with a QRS score <6 achieved exercise tolerance >5 minutes, whereas all patients who could not exercise >5 minutes had a QRS score >5.

The relation between QRS score and reasons for termination of the test is shown in Figure 5. Patients with fatigue or dyspnea, or both, had a significantly higher QRS score compared with those in target heart rate and those in completed protocol (8.7 ± 4.6 versus 5.4 ± 2.2 and 3.0 ± 1.7, $p < 0.05$ and $p < 0.01$, respectively), whereas chest pain had an intermediate QRS score (5.3 ± 2.7).

Regarding the relation between QRS score and S-T segment changes during low level exercise testing, patients showing S-T changes during the exercise test had a significantly higher QRS score than did patients with no S-T changes (8.2 ± 4.5 versus 4.7 ± 2.8, $p < 0.05$).

Discussion

Electrocardiographic assessment of left ventricular function in AMI: Correlations between left ventricular function and changes in the QRS complex in electrocardiograms have been demonstrated. Awan et al[26] demonstrated a significant correlation between the number of pathologic Q waves in a 35-lead precordial mapping and LVEF in patients with anterior AMI. Askenazi et al[27] reported a significant correlation between the sum of R-wave amplitude in a standard electrocardiogram and LVEF in patients with chronic coronary artery disease. In the present study, a recently developed QRS scoring system using standard 12-lead electrocardiograms was studied; this system was established by Palmeri et al[18] and Wagner et al[19] based on computer simulation of sequence in the ventricular activation process.[28–30]

In their first clinical study, they manifested significant correlations between QRS score and LVEF using electrocardiography and radionuclide ventriculography taken 3 and 8 weeks after the onset of AMI. In their most recent study,[31] they correlated QRS score with pathologic infarct size in patients with anterior MI and demonstrated a significant correlation between QRS score and percent infarction of the left ventricle.

Our results magnify the clinical values of their QRS scoring system. QRS scoring using electrocardiograms taken 7 days after the onset of AMI has also significantly correlated with both early stage LVEF and enzymatically estimated infarct size. It seemed to be more reasonable and clinically available.

As for early stage LVEF in AMI, Shah et al[5] demonstrated its clinical value as a prognostic indicator, predicting hospital morbidity and mortality from pump failure. Although it was not the principal object in the present study, short-term follow-up (6 to 15 months) of 42 patients in the correlation study revealed that 10 patients died in this follow-up period; in 4 of these patients the QRS scores were 5, 7, 12, and 13, and intraventricular conduction delay was present in the other 6 patients. In these 10 patients, 6 had early stage LVEF <30%. Shah et al[5,23] reported that death because of pump failure occurred at a higher rate (>50%) in patients with early stage LVEF <30%. We confirmed a similar finding in the present study.

Regarding the prognostic implications of electrocardiograms after myocardial infarction, the Coronary Drug Project Research Group[32] reported that the presence of abnormal Q waves, S-T displacements, intraventricular conduction delay, or arrhythmias, or a combination of these, in resting electrocardiograms was importantly related to mortality over a 3-year follow-up period. Wasserman et al[33] also recently reported that patients with multiple Q-wave locations or with Minnesota Code major criteria of infarction based on Q-wave duration and Q/R amplitude ratios had significantly higher mortality rates during a 3-year follow-up period. Their reports agree with our follow-up observations. Further studies are required to determine the prognostic value of the QRS scoring system in AMI.

A number of studies have examined the correlation between enzymatically estimated infarct size and LVEF,[34,35] cardiac hemodynamics, or prognosis.[9,36–38] However, the present study is the first to document that the QRS scoring system by Palmeri, Wagner and their group[18,19] also correlated well with the enzymatically estimated infarct size in patients with AMI. The advantage of this QRS scoring system is that it is inexpensive, readily accomplished using standard electrocardiograms, and universally available for assessing infarct size and LVEF.

QRS scoring and exercise performance soon after AMI: Furthermore, the relation of QRS scoring to exercise performance was revealed. The QRS score would be useful for early identification of patients with higher exercise tolerance, because all patients with a QRS score <6 achieved exercise tolerance >5 minutes in this study. Moreover, the QRS scoring was significantly related to the symptoms during low level exercise testing soon after AMI. From these results, it is presumed that patients with a higher QRS score would have limited exercise tolerance because of symptoms of dyspnea or fatigue or reaching target heart rate in the early stage.

Dillahunt et al[39] reported that the ability to exercise ≥5 minutes on the treadmill at 1 mph, 0% grade, identified single-vessel disease in most patients. In our study, angiographic correlation was not investigated, although our results agreed with their findings, namely, patients with a QRS score <6 (equal to exercise tolerance >5 minutes) would have a smaller infarct and a greater LVEF. Paine et al[40] reported the significant correlation between exercise tolerance and LVEF and also between exercise tolerance and angiographic scar size (percent of abnormally contracting segment) estimated from left ventriculography in patients with previous myocardial infarction. Further, Weld et al[41] revealed that shorter exercise tolerance was strongly associated with cardiac death in the first year of follow-up. QRS scoring would be clinically important in early identification of exercise performance and also for prognostic implications combined with exercise test results.

The findings that the QRS score was higher in patients with than in those without exercise S-T changes suggested that S-T changes during low level exercise testing would develop in patients with a larger infarct and a lower LVEF period. Starling et al[42] reported that coronary events after the first AMI were more common in patients with exercise-induced S-T changes, anginal pain, or an inadequate blood pressure response. Therefore, it is suggested that patients with a higher QRS score, shorter exercise tolerance, and exercise-induced S-T changes would be consistent with these patients who are at risk for a future cardiac event.

Multiform Accelerated Idioventricular Rhythm in Acute Myocardial Infarction: Electrocardiographic Characteristics And Response to Verapamil

SAMUEL SCLAROVSKY, MD, BORIS STRASBERG, MD, JACOB FUCHS, MD, RUBEN F. LEWIN, MD, ALEXANDER ARDITI, MD, ELIEZER KLAINMAN, MD, OSCAR H. KRACOFF, MD, and JACOB AGMON, MD

Thirteen patients with acute myocardial infarction with multiform accelerated idioventricular rhythm (AIVR) occurring during the first 12 hours of monitoring in the coronary care unit are described. This arrhythmia, similar to the more common uniform AIVR, was intermittent, did not cause hemodynamic compromise, and was not related to more serious ventricular arrhythmias. There was no correlation between the bundle branch block pattern of the multiform AIVR and the electrocardiographic location of the myocardial infarction, but there was a perfect correlation between the frontal plane electrical axis of the multiform AIVR and the electrocardiographic location of the myocardial infarction. The presence of fusion beats between the different forms of AIVR suggests multifocality rather than multiformity.

Intravenous verapamil (3 to 5 mg bolus) was administered to 6 patients with multiform AIVR in whom the arrhythmias were persistent enough to allow the evaluation of the effect of verapamil on the arrhythmia. Verapamil caused no change in the rate of AIVR in 1 patient, but in a second patient it decreased the rate by 20 beats/min. In 4 patients, verapamil abolished the arrhythmia: in 2 patients carotid sinus pressure (induced sinus slowing) allowed the emergence of the AIVR at a lower rate, and in the remaining 2 patients the arrhythmia was not observed.

In the last 4 years we have evaluated patients admitted to our coronary care unit with acute myocardial infarction (MI) in whom accelerated idioventricular rhythm (AIVR) developed. In 13 cases a multiform variety of AIVR was observed. In this report we present our experience with multiform AIVR and compare it with the reported experience with the more common uniform AIVR. In addition, we administered intravenous verapamil to 6 patients with multiform AIVR in whom the arrhythmia was long enough to evaluate the effect of the drug.

Methods

The diagnosis of acute MI was based on a typical clinical history and enzymatic curve together with typical electrocardiographic changes including the development of pathological Q-waves. The MI was considered anterior when the electrocardiographic changes included precordial leads V_1 to V_4 (anteroseptal MI) and/or leads V_2 to V_6 (anterolateral MI), while inferior MI included leads II and III and aVF.

AIVR was defined according to established criteria[1] which included (1) a ventricular rhythm with a rate of 50 to 125 beats/min; (2) initiation with an escape beat, fusion beat, or a late premature depolarization appearing during a slowing phase of the sinus rhythm; (3) a regular R-R interval; (4) termination with a return to sinus rhythm with or without fusion beats. Multiform AIVR was diagnosed when at least 2 different QRS morphologies of AIVR were detected. Four cases were previously partially reported.[2]

Once AIVR was detected, patients were connected to a 3-channel electrocardiogram. All cases of multiform AIVR were evaluated for up to 12 hours in order to study its natural evolution. Electrocardiographic leads aVR, aVL, and aVF were used to define the characteristic QRS morphology of each form of AIVR recorded and for purposes of follow-up study. Lead aVR determined the bundle branch block (BBB) morphology of the AVIR,[3] after corroboration with lead V_1; a right BBB morphology was characterized by a dominant R-wave and a left BBB was characterized by a dominant S-wave. Leads aVL and aVF were used for axis determination. Left-axis deviation was characterized by a positive complex in aVL and a negative complex in aVF, and right-axis deviation was characterized by a negative QRS complex in aVL and a posi-

tive QRS complex in aVF. Multiform AIVR was therefore divided into 5 morphologic subgroups: (1) right BBB and left-axis deviation morphology; (2) right BBB and right-axis deviation morphology; (3) left BBB and left-axis deviation morphology; (4) left BBB right-axis deviation morphology; (5) undetermined BBB or axis deviation morphology.

Verapamil was administered as an intravenous bolus of 3 to 5 mg under electrocardiographic and blood pressure control. In case of disappearance of the arrhythmia after the administration of verapamil, carotid sinus pressure was applied to induce sinus slowing and facilitate the emergence of the ectopic rhythm.

Results

Clinical characteristics: There are 11 men and 2 women with ages ranging from 40 to 79 years (mean 60). The acute MI was electrocardiographically located to the anterior wall in 4 patients, to the inferior wall in 5 patients, and to both walls in 4 patients.

Characteristics of multiform AIVR: Multiform AIVR was of transient duration, did not cause hemodynamic compromise, and was not associated with serious ventricular arrhythmias; therefore, in no case was there a need for medical treatment.

Multiform AIVR with 2 different morphologies was detected in 7 cases, with 3 different morphologies in 5 cases, and with 4 different morphologies in 1 case (Fig. 1A and 2). In patients with anterior MI, the observed multiform AIVR morphologies were of right or left BBB pattern and always with right-axis deviation. In patients with inferior MI, the observed multiform AIVR morphologies were of right or left BBB pattern and always with left-axis deviation. In patients with combined anterior and inferior MI, the observed multiform AIVR morphologies were of right or left BBB and with right- and left-axis deviation or in 1 case with undetermined axis.

Multiform AIVR was first seen 3 hours after admission to the coronary care unit but was widely distributed during the subsequent 9 hours of evaluation. Different forms of AIVR were seen independently at different times but generally the 2 or 3 different forms of AIVR were seen to interchange between them with or without the occurrence of fusion beats (Fig. 1 and 2). These fusion beats occurred between the ectopic focus and sinus rhythm or between the 2 forms of AIVR (Fig. 1).

Response to verapamil: Six patients received intravenous verapamil. The first patient received various boluses (with 5-minute intervals between boluses) of only 3 mg of intravenous verapamil. The low amounts of verapamil were given to preclude hemodynamic compromise. In this patient, no change in the rate of the AIVR was seen. The remaining 5 patients received a 3 to 5 mg bolus of verapamil. In 1 patient, a decrease of the rate of the AIVR of 20 beats/min was observed (Fig. 1). In the remaining 4 patients, the AIVR disappeared. After the administration of verapamil and the disappearance of AIVR, carotid sinus massage was applied to these 4 patients (induced sinus slowing or arrest) in order to avoid any possible overdrive suppression of the AIVR. In 2 patients, despite adequate slowing, AIVR

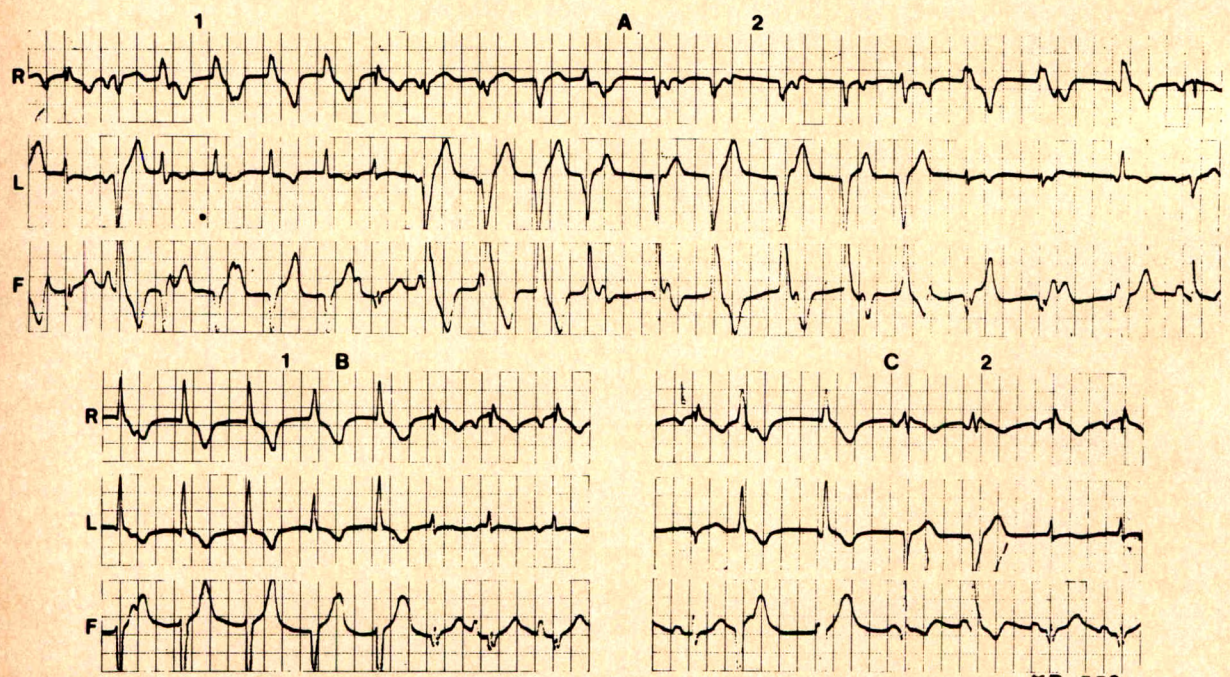

FIGURE 1. Example of multiform accelerated idioventricular rhythm (AIVR) of 2 different QRS morphologies and the effect of verapamil. All tracings were recorded with a 3-channel electrocardiogram with leads aVR, aVL, and aVF. **A**, 2 forms (1 and 2) of AIVR are observed. Form 1 has a right BBB morphology, left-axis deviation, and a rate of 100 beats/min. Form 2 has a left BBB morphology, right-axis deviation, and a rate of 95 beats/min. AIVR of form 1 changed to form 2 with the occurrence of a fusion beat between a sinus beat and AIVR form 1 (7th QRS of the strip). Subsequently, AIVR of form 2 reverted to form 1 with fusion beats between both forms (17th and 18th QRS of the strip). After the administration of verapamil (**lower panels**), AIVR of form 1 (**B**) is observed at a rate of 80 beats/min and AIVR of form 2 (**C**), which are fusion beats, are observed at a rate of 75 beats/min.

was not observed (Fig. 3). In the other 2 patients a similar form of AIVR, but at a slower rate, was observed once enough slowing of the sinus rhythm was obtained with carotid massage (Fig. 4).

Discussion

Uniform AIVR is an arrhythmia of ectopic ventricular origin occurring most commonly during the first 24 hours of an acute MI; its course is generally benign and there is no need for treatment.[4] We[5] reported on 2 patients with MI who had 2 different morphologies of AIVR. In both cases, the arrhythmia occurred during the first hour after admission to the hospital, and it had a transient nature and a benign course, similar to the course described for uniform AIVR. Since our initial observation, we have detected 13 additional patients with multiform AIVR. The reason for this is mainly the use of a 3-channel electrocardiogram with frequent recordings during the first 12 hours of the admission to the coronary care unit. The evolution observed for multiform AIVR was similar to the described evolution of uniform AIVR. The arrhythmia appeared during the first 24 hours of the MI, it had a transient duration, it did not cause hemodynamic compromise, and it did not degenerate or induce more serious ventricular arrhythmias. Therefore, as in uniform AIVR there seems to be no need for treatment.

The different morphologies of AIVR were scattered during the 12 hours of recording. Usually there was a predominant form of AIVR at 1 determined time of the recording. Once 1 form of AIVR would emerge and disappear, a lapse of several hours could be observed until the emergence of a second or third form of AIVR. When 2 forms of AIVR would compete for dominance of the heart rhythm, they usually interchanged with fusion beats between them. The fact that different forms of AIVR would appear several hours after the appearance of uniform AIVR indicates that multiform AIVR could indeed be a more common arrhythmia; many cases of uniform AIVR, if followed carefully and with 3-channel electrocardiographic recording, will show a multiform morphology. Additionally, it was of interest to observe fusion beats between different forms of AIVR. It has been demonstrated that different QRS morphologies could be the expression of different patterns of activation of a single ectopic foci.[6–9] Therefore, the term *multiform* is preferred to *multifocal.* Nevertheless, the presence of different degrees of fusion beats between these different AIVR forms suggest multifocality rather than multiformity. It is conceivable that different areas of abnormal automatism (expressed as AIVR) emerge simultaneously or at different times in the infarcted myocardium developing a multiform variety of AIVR.

Multiform AIVR morphology and acute MI location: The QRS configuration of ventricular ectopic beats has been used to try to determine its site of origin. In the absence of organic heart disease, the BBB pattern of premature ventricular complexes usually indicates the ventricle of origin.[10] In addition, the work of Mautner and Girotti,[11] Rosenbaum,[12] and Waxman and Josephson[13] suggests that the electrical axis of the ventricular premature beats are related to its site of origin. In ischemic heart disease, it has been demonstrated that the QRS configuration cannot be utilized to determine the site of origin of ventricular tachycardia.[8] Despite the above observation, in a previous study, we observed a 90% correlation between the origin of

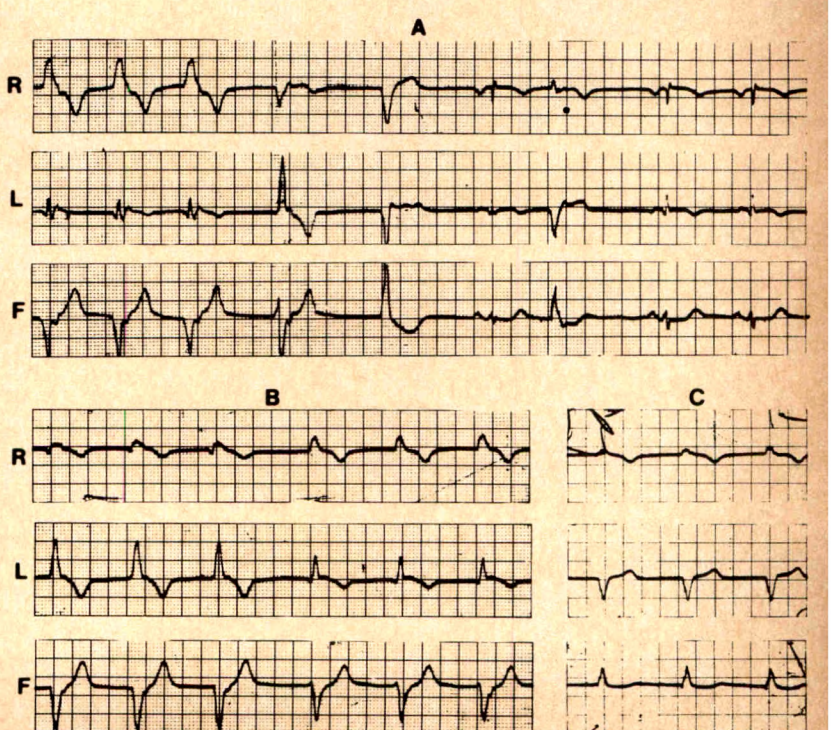

FIGURE 2. Example of AIVR with 4 different forms. **A**, the first 3 beats represent an AIVR with right BBB morphology and "undetermined axis." **B**, 2 additional forms of AIVR. Both forms have right BBB morphology and left-axis deviation, but they differ in the first QRS vector. **C**, the fourth form of AIVR with right BBB morphology and right-axis deviation.

premature ventricular contraction appearing during acute MI and the location of the infarction as determined by the electrocardiogram.[14] In the present study, the type of BBB of the multiform AIVR did not correlate with the electrocardiographic location of the acute MI, since virtually in all patients both right and left BBB morphologies were observed. In contrast, we observed a good correlation between the electrocardiographic site of the infarction and the electrical axis of the AIVR. In patients with acute inferior MI, the AIVR (irrespective of the BBB pattern) always had a left-axis deviation pattern suggesting an inferior origin of the ectopic rhythm; however, in patients with anterior MI, a right-axis deviation was observed, suggesting an anterior site of origin. In patients with combined MI, both right- and left-axis deviation were observed. The findings in our previous study of a relationship between premature ventricular contractions morphology and the electrocardiographic location of the acute MI and the finding in the present study of the relationship of AIVR morphology (axis deviation) and the electrocardiographic location of the acute MI suggests an origin for the ectopic ventricular rhythm in the area of acute MI.

Electrophysiologic features of AIVR and the effect of verapamil: AIVR occurs in the late arrhythmic phase (phase II) of acute MI.[4] The mechanism of AIVR is not clearly understood but it is postulated that abnormal automaticity in the subendocardial Purkinje fibers under the infarct is the responsible mechanism for this arrhythmia.[4] In addition, abnormal automaticity in acute MI has been related to the slow inward current[3,15] and therefore it could be expected to be suppressed by verapamil, a drug that mainly inhibits the slow inward current.

In this study, verapamil was administered to 6 patients with AIVR. In 1 patient no effect on the arrhythmia was observed. This patient received low boluses (3 mg) of verapamil because of fear of hemodynamic compromise. It is possible that with higher doses of verapamil, an effect on AIVR would have been apparent. In 5 patients, an effect of verapamil on AIVR was observed. In 1 patient a decrease in the rate of the AIVR was observed, and in the remaining 4 patients the arrhythmia disappeared. Carotid sinus massage was applied in all these responders; in 2 patients the same ectopic rhythm at a lower rate could be demonstrated and in the remaining 2 patients no ectopic rhythm was observed. The effect of verapamil on this arrhythmia is further evidence of the role of the slow inward current in the genesis of venticular arrhythmias during acute MI.

Clinical implication: AIVR is generally considered a benign arrhythmia, even though studies contradicting these results have been reported. Multiform AIVR is a variety of AIVR with identical pathophysiologic features and clinical course. We believe that the incidence of multiform AIVR is higher than expected and is related to type, length, and degree of monitoring. Since multiformity has been considered an indicator of the

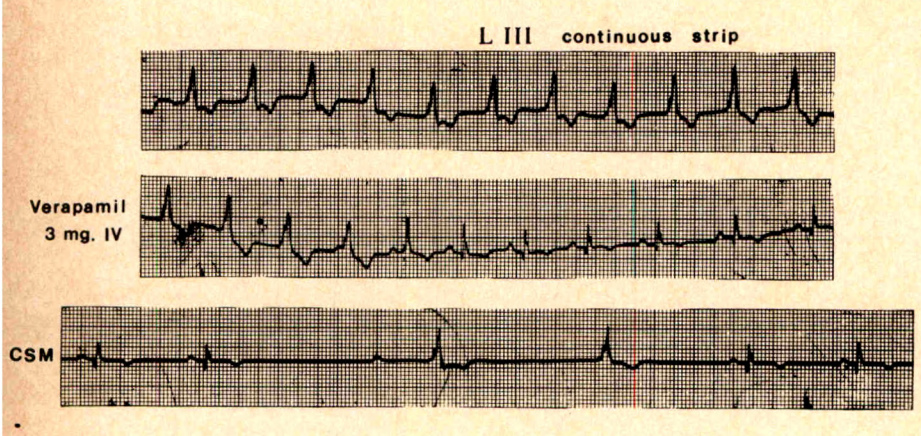

FIGURE 3. Administration of verapamil to a sustained bout of AIVR results in termination of the arrhythmia apparently due to sinus rhythm overdrive suppression, but carotid sinus massage (CSM) fails to uncover the presence of AIVR and shows 2 ventricular escape beats of morphology similar to the AIVR. IV = intravenous; LIII = lead III.

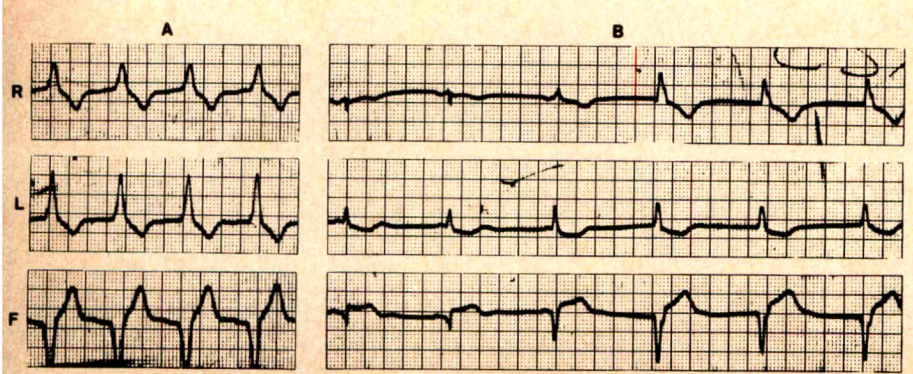

FIGURE 4. Effect of verapamil on AIVR. **A**, an episode of AIVR with a rate of 80 beats/min. Administration of verapamil resulted in disappearance of AIVR. Carotid sinus pressure (**B**) caused sinus slowing, allowing the emergence of a similar form of AIVR at a rate of 55 beats/min. F = lead aVF; L = lead aVL; R = lead aVR.

degree of severity and danger of premature ventricular contractions occurring during acute MI, it is worth emphasizing the benign nature of this multiform rhythm. Finally, the effects of verapamil on this rhythm offer new evidence of the role of the slow inward current in the genesis of arrhythmia occurring during acute MI.

Addendum

We administered verapamil to 2 patients (4 and 5 mg, respectively) with frequent and short bouts of uniform AIVR. In these cases, carotid sinus pressure reproducibly facilitated the emergence (due to sinus slowing) of the AIVR. After the administration of verapamil, application of carotid sinus massage caused a higher degree of sinus slowing but without the reemergence of AIVR.

Subcostal 2-Dimensional Echocardiographic Imaging of Peripheral Left Coronary Artery Aneurysms in Kawasaki Disease

TOSHIKI MAEDA, MD, HITOSHI YOSHIDA, MD, TAKASHI FUNABASHI, MD, SHIGEKAZU NAKAYA, MD, SHOJI TAKABATAKE, MD, TAKASHI OHNO, MD, and NOBORU TANIGUCHI, MD

Our previous study provided a new 2-dimensional echocardiographic technique to detect peripheral right coronary artery aneurysms in Kawasaki disease, with use of the subcostal approach. An additional study was performed to detect peripheral left coronary artery aneurysms. Because the left anterior descending artery runs along the anterior interventricular sulcus and the left circumflex artery along the mitral valve ring, these regions were searched for coronary aneurysms by use of the subcostal imaging approach. Among 143 patients with Kawasaki disease, 44 left coronary aneurysms were visualized in 22 patients. Three aneurysms at the origin of the obtuse marginal artery and 1 in the further peripheral site of the left circumflex artery were observed in 3 patients. Two aneurysms at the origin of the second diagonal branch of the peripheral left anterior descending artery were detected. These echocardiographic studies were done prospectively, and their features coincided well in size, shape, and anatomic location with confirmatory angiographic appearances.

Recognition of coronary aneurysms by noninvasive methods is useful in following up patients with Kawasaki disease because coronary aneurysm is an ominous complication that carries a risk of sudden death.[1–9] Two-dimensional (2-D) echocardiography can be used to visualize coronary aneurysms using the parasternal horizontal approach at the level of the aorta.[10–13] However, this approach visualizes only limited areas of the proximal segments of the coronary arteries. In our previous study, we described a technique for detecting peripheral coronary aneurysms of the right coronary artery.[14] In the present study, we describe a technique for detecting peripheral coronary aneurysms of the left coronary artery from the ostium to terminal sites in both the left anterior descending (LAD) and left circumflex (LC) arteries, using the subcostal approach.

Methods

Two-dimensional echocardiograms were recorded in 143 patients with Kawasaki disease (86 male and 57 female), aged 2 months to 8 years, whose conditions were assessed on the basis of guidelines prepared by the Japanese Research Committee in 1978. Coronary angiography was performed in 34 patients with Kawasaki disease: 31 patients were suspected of having coronary aneurysms on 2-D echocardiography. The other 3 patients had no positive findings on 2-D echocardiography but were severely affected on the basis of clinical features and laboratory data.

We performed this study using a real-time mechanical sector instrument (Aloka SSD 1000 with ASU 25 hand scanner and USM 6B amplifier). The scanner probe, which contained a 3 MHz transducer focused at 7.5 cm, was mechanically driven through a variable angle (30° to 80°) at a rate of 30 frames/s, yielding a line density of approximately 110 lines/frame. Two-dimensional echocardiographic images were observed in real time during the examinations. The images, which were displayed as phase-selected single frames, were photographed directly from the oscilloscope screen with a Polaroid® camera, and real-time images were recorded with a 16 mm cinecamera and analyzed subsequently in real-time, slow motion, and single format.

Anatomically, the left main coronary artery originates from the left coronary sinus and passes between the pulmonary trunk in the front and left atrial appendage behind. A short distance from its origin, usually a few millimeters in infants and children, it divides into LAD and LC arteries. The LAD artery passes downward over the anterior surface of the heart along the full length of the anterior interventricular sulcus and onto the inferior surface. The LC artery departs at an acute angle from the left main coronary artery to run posteriorly along the atrioventricular groove, toward the crux cordis.

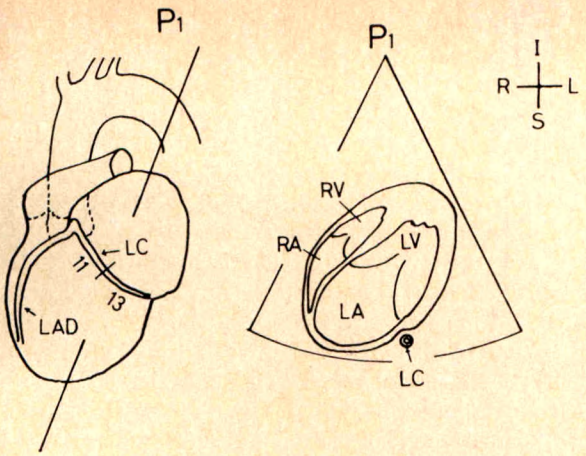

FIGURE 1. Schematic drawings of the subcostal view for imaging coronary aneurysms in segments 11 and 13 of the left circumflex artery. **Left,** the position of sector P1, showing a view of the 4 chambers. The left circumflex aneurysms can be detected at the left side of the mitral valve. I = inferior; L = left; LA = left atrium; LAD = left anterior descending artery; LC = left circumflex artery; LV = left ventricle; R = right; RA = right atrium; RV = right ventricle; S = superior; 11 and 13 = segments 11 and 13.

Throughout this course, the LC artery encircles the mitral valve ring.[15–17]

The subcostal approach that we developed for imaging peripheral coronary aneurysms of the left coronary artery consists of 2 parts. The first is a subcostal frontal approach (Fig. 1). The scanner probe was initially oriented so that the sector beam was directed through the heart on a plane parallel to a line between the patient's shoulders, allowing simultaneous visualization of the 4 chambers (sector P1).[18,19] In the section, the LC artery runs along the left side of the mitral valve ring. The scan plane was angled more posteriorly for imaging the peripheral site of the LC artery, that is, segment 13 (segment classification according to American Hea Committee Report[20]).

The second part is a subcostal sagittal approach (Fig. 2 The section was first positioned roughly parallel to a plan cutting both the long axes of the sternum and spinal colum allowing simultaneous visualization of the right ventricula outflow tract, pulmonary valves, interventricular septun mitral valve, and left atrium (sector P2).[21] Next, the secto plane was angled to the left as plane P3 in Figure 2. In secto P2 and P3, the peripheral LC artery (segment 13) runs alon the inferoposterior side of the mitral valve ring. By scannin sectors P2 and P3, the inferoposterior area of the mitral valv ring was examined for coronary aneurysms. Then the secto plane was tilted more to the left, with the left atrium ju disappearing, so that the left ventricular cavity was image in the short axis (sector P4). In this sector, the LC artery ca be seen running along the supraposterior side of the left ven tricle around the mitral valve ring, and the LAD artery run along the superior side of the interventricular septum. Th sector plane was tilted more to the cardiac apex (sector P so that the LAD runs along the superior side of the interven tricular septum.

Technical considerations involved in recording coronar aneurysms must be done with this subcostal sagittal approach Particularly in sectors P2 and P3, the interventricular septu must be differentiated from the tricuspid valve. The tricuspi valve will be imaged slightly angled to the right and can b distinguished by its shape and motion. Also, it would be ver helpful to use a peripheral vein contrast echo that distin guishes the tricuspid valve and interventricular septum, be cause the tricuspid valve would be filled with contrast echoe The mitral valve, which is posterior to the interventricula septum, would be differentiated from the other structures the heart by confirming the interventricular septum.

Results

Among 143 patients with Kawasaki disease, le coronary aneurysms were visualized in 22 patients b 2-D echocardiography, including the proximal seg ments. Concerning the peripheral left coronary arter

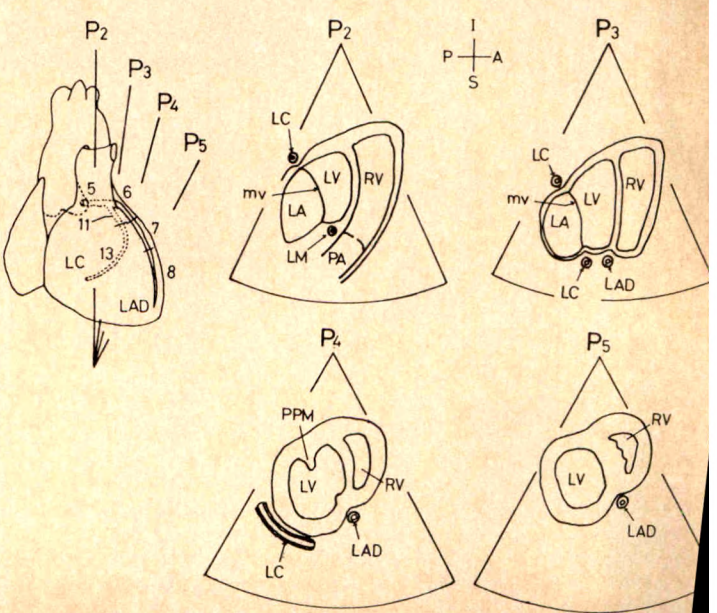

FIGURE 2. Schematic drawings of the subcostal views for imaging coronary aneurysms in segments 6, 7, and 8 of the left anterior descending artery and segments 11 and 13 of the left circumflex artery. The **top left panel** shows the position of sectors P2, P3, P4, and P5. Scanning from P2 to P4, coronary aneurysms of the left circumflex artery can be detected. Scanning from P3 to P5, coronary aneurysms of the left anterior descending artery can be detected. A = anterior; I = inferior; LA = left atrium; LAD = left anterior descending artery; LC = left circumflex artery; LM = left main coronary artery; LV = left ventricle; mv = mitral valve; P = posterior; PPM = posterior papillary muscle; RV = right ventricle; S = superior; 5, 6, 7, 8, 11, and 13 = segments 5, 6, 7, 8, 11 and 13.

6 aneurysms (3 in the LC artery at the origin of the obtuse marginal artery, 1 in segment 13, and 2 in the LAD artery at the origin of the second diagonal branch) were detected with the subcostal approach. The echocardiographic findings of these 6 peripheral left coronary aneurysms almost coincided in size, shape, and anatomic position with angiographic features found later. However, coronary angiography, performed in all 34 patients suspected of having right or left coronary aneurysms, or both, by 2-D echocardiography and clinical findings, showed 2 aneurysms in segment 13 in 1 patient (Fig. 3). These 2 aneurysms were located at the origins of the posterolateral branch and the posterior descending branch and at first were regarded as 1 aneurysm in segment 13 by 2-D echocardography.

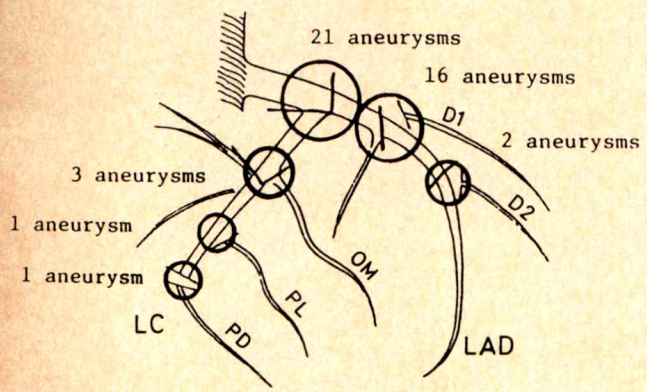

FIGURE 3. The number of left coronary aneurysms in each location by angiography. Forty-four left coronary aneurysms were shown in 22 patients with Kawasaki disease. D1 = first diagonal branch; D2 = second diagonal branch; LAD = left anterior descending artery; LC = left circumflex artery; OM = obtuse marginal artery; PD = posterior descending branch; PL = posterolateral branch.

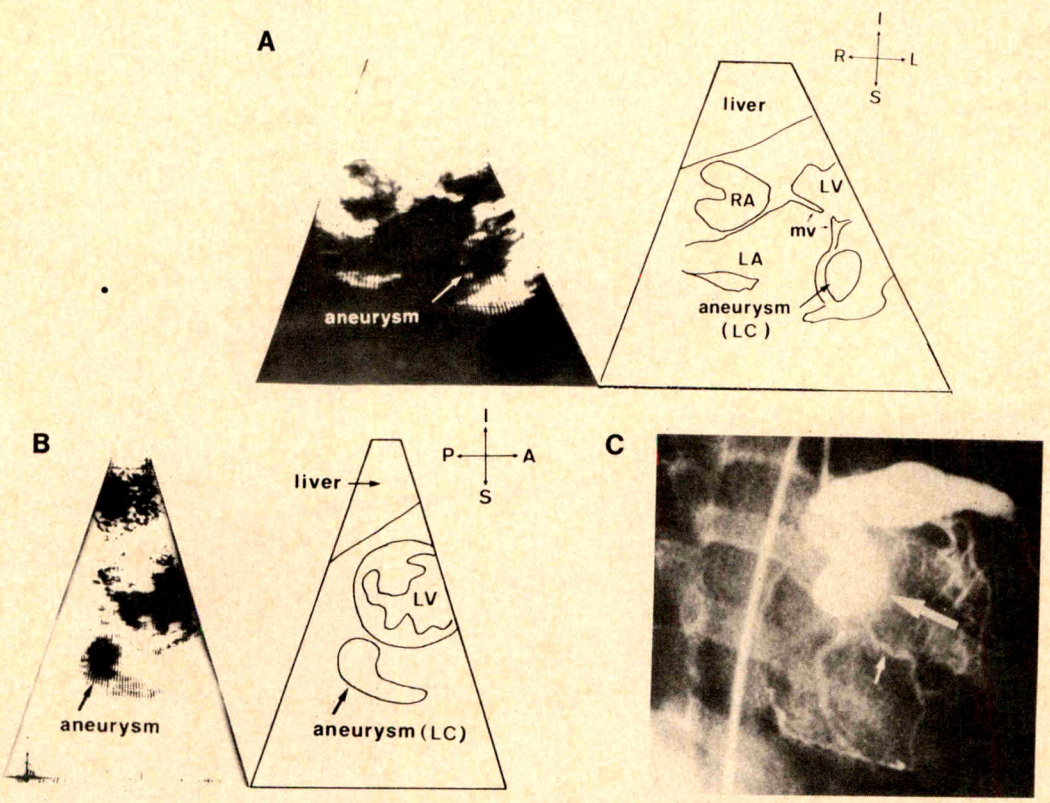
Figure 4A, a 2-D echocardiogram in sector P1 from a patient with Kawasaki disease, shows an abnormal oval echo-free space, approximately 6 by 5 mm, at the left side of the mitral valve. This space was also imaged at the supraposterior side of the left ventricle around the mitral valve ring in sector P4 (Fig. 4B). The coronary aniogram (Fig. 4C) shows a coronary aneurysm at the origin of the obtuse marginal artery.

Figure 5A, a 2-D echocardiogram in sector P3 from a patient with Kawasaki disease, shows 3 abnormal echo-free spaces. One of these, approximately 4 by 4 mm, is seen at the inferior side of the mitral valve, adjacent to the liver. The coronary angiogram shows it to be a peripheral LC aneurysm in segment 13 (Fig. 5B). Another echo-free space, which the coronary angiogram (Fig. 5B) disclosed to be an aneurysm of the proximal LC artery, is visualized at the superior side of the mitral valve. The other echo-free space, which the coronary angiogram disclosed to be an aneurysm of the proximal



URE 4. Two-dimensional echocardiograms and coronary angiogram from a 1-year-old boy with Kawasaki disease. **A,** sector P1 showing an normal echo-free space (**arrow**) at the left side of the mitral valve. **B,** sector P4 showing the same coronary aneurysm as in **A. C,** angiogram wing 2 coronary aneurysms (30° right anterior oblique view). A coronary aneurysm (**large arrow**) at the origin of the obtuse marginal artery all **arrow**) corresponds to echo-free spaces in **A** and **B**. LAD artery, is visualized at the superior side of the interventricular septum.

Figure 6A, a 2-D echocardiogram in sector P5 from a patient with Kawasaki disease, shows an oval echo-free space, approximately 3 by 2 mm, at the superior side of the interventricular septum. The coronary angiogram (Fig. 6B) shows a coronary aneurysm of the portion where the LAD artery branches off the second diagonal branch.

Discussion

Stenosis and obstruction of the coronary artery with Kawasaki disease, which carry a risk of sudden death, commonly occur in the front and rear of aneurysms. It is therefore important to recognize aneurysms in Kawasaki disease in order to determine the prognosis because stenotic and obstructive changes of the coronary artery cannot be easily visualized with 2-D echocardiography. It has been reported that the parasternal horizontal approach at the level of the aorta by 2-D echocardiography can visualize the proximal segment of the coronary artery.[10–13] However, this approach can image the coronary artery for only a few millimeters from the ostium. In a previous study, we described a new method of searching for peripheral right coronary aneurysms.[14] In the present study, we initiated a method of detecting peripheral left coronary aneurysm in both the LAD and LC arteries by using the subcostal approach. This method allowed the visualization of peripheral coronary aneurysms that could not be detected

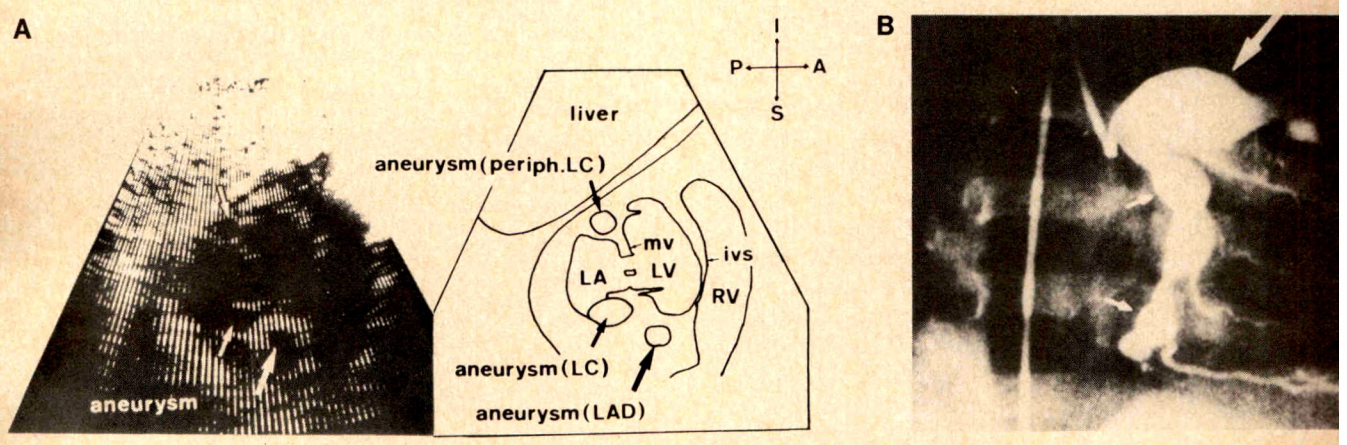

FIGURE 5. Two-dimensional echocardiogram and coronary angiogram from a 2-year-old boy with Kawasaki disease. **A,** sector P3 showing 3 abnorma echo-free spaces. One space is seen at the inferior side of the mitral valve (**upper small arrow**). Another is seen at the superior side of the mitra valve (**lower small arrow**). The other space is seen at the superior side of the interventricular septum (**large arrow**). **B,** angiogram showing severa aneurysms of the left coronary artery (30° right anterior oblique view). The **large arrow** corresponds to the **large arrow** in **A**. The **upper small arrow** corresponds to the **lower small arrow** in **A.** The **lower small arrow** corresponds to the **upper small arrow** in **A**. A = anterior; I = inferior; ivs = interventricular septum; LA = left atrium; LAD = left anterior descending artery; LC = left circumflex artery; LV = left ventricle; mv = mitral valve P = posterior; periph. LC = peripheral left circumflex artery; RV = right ventricle; S = superior.

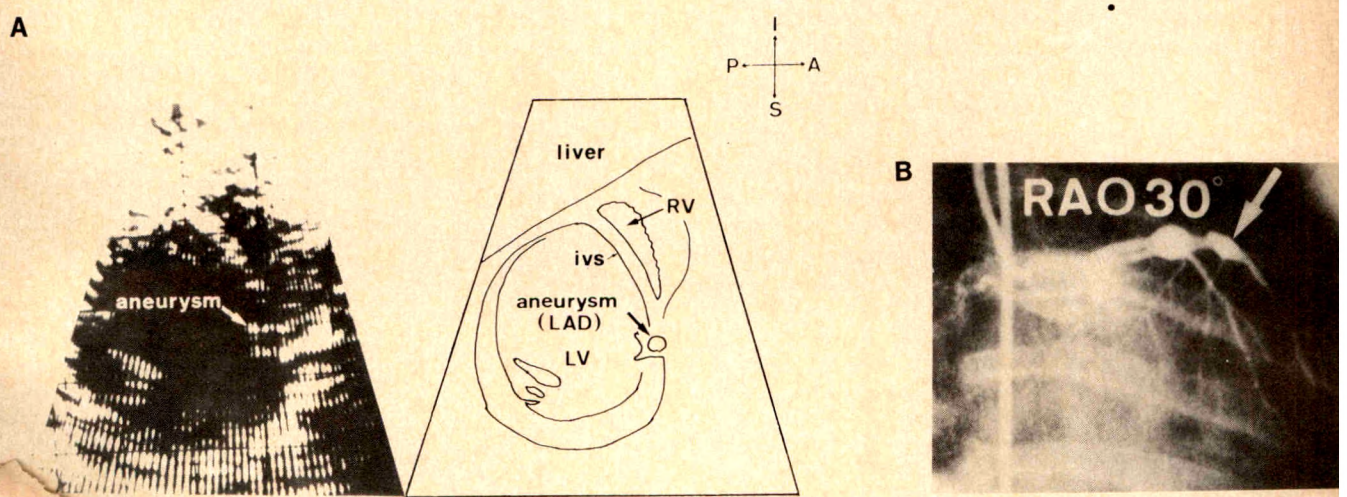

Two-dimensional echocardiogram and coronary angiogram from an 8-month-old boy with Kawasaki disease. **A,** sector P5 showing a e space at the superior side of the interventricular septum. **B,** angiogram revealing 4 coronary aneurysms. with the parasternal horizontal approach. The images of the peripheral left coronary aneurysms, although not perfect, coincided well in size, shape, and anatomic position with the angiographic appearances later confirmed. With regard to the proximal segments, the parasternal horizontal approach is better than the subcostal approach because the former can detect coronary arteries on a long axis.

In this study, why the peripheral coronary aneurysms were not detected in the parasternal or apical approach without large aneurysms is an important question. The peripheral LAD aneurysms could be visualized using the parasternal short-axis view of the left ventricle at the level of the mitral valve papillary muscles. The parasternal short-axis view of the left ventricle at the level of the mitral valve ring and a parasternal or apical 4-chamber view should be useful for visualizing the peripheral portion of the LC artery. It is probable that we were not able to visualize peripheral coronary artery aneurysms in the parasternal views because we used a 3 MHz transducer focused at 7.5 cm. If we had used a transducer with a shorter focus, we might have been able to see these aneurysms from the precordial views.

Although the peripheral coronary artery, in normal infants and children, could not be visualized with the subcostal approach, we were able to image the dilatation of the peripheral LC artery (approximately 2 by 2 mm) because of Kawasaki disease in sectors P2 and P3. This technique may be limited in distinguishing small coronary aneurysms from the normal coronary artery because the peripheral segments of the left coronary artery are cut in slices. Therefore we had to obtain confirmation by angiography in all patients whose peripheral left coronary arterial echo-free spaces were visualized by subcostal approach. Because patients who underwent angiography were selected largely on the basis of their echocardiographic and clinical findings, we were unable to make any statements about false-negative results in the detection of peripheral coronary artery aneurysms. Further comparative studies with both echocardiography and coronary angiography may be required in many cases.

The parasternal horizontal approach is a good technique as it can image even the normal coronary artery on a long axis, but it can image only limited areas of proximal segments. Our previous study provided a technique for detecting peripheral right coronary aneurysms with use of the subcostal approach.[14] In the present study, we describe a new technique for detecting peripheral left coronary aneurysms in both LAD and LC arteries. By combining these 3 techniques, almost all coronary aneurysms, located in either the proximal or the distal artery, can be visualized with 2-D echocardiography.

CME Test #1

Intracoronary Thrombus in Nontransmural Myocardial Infarction and in Unstable Angina Pectoris*

The University of Alabama School of Medicine designates this continuing medical education activity for 1 credit hou in Category 1 of the Physician's Recognition Award of the American Medical Association. Answers are to be marke on instruction sheet on page 176.

1. Intracoronary thrombus clearly plays an important role in:
   a) acute transmural myocardial infarction
   b) nontransmural myocardial infarction
   c) unstable angina
   d) none of the above

2. Patients for this study were selected according to the presence of:
   a) an identifiable ischemia-related vessel
   b) bleeding diatheses
   c) hemorrhagic peptic ulcer disease
   d) recent cerebral vascular disease

3. Patients were selected who had:
   a) isolated coronary artery stenosis <60%
   b) isolated coronary artery stenosis >60%
   c) isolated coronary artery stenosis >70%
   d) had recent surgery

4. To determine percentages of stenosis, the narrowest stenotic diameter was compared with:
   a) the widest stenotic diameter
   b) the diameter of the nearest uninvolved distal segment
   c) the diameter of the nearest uninvolved proximal segment
   d) all the above

5. A positive anatomic response to nitroglycemia or streptokinase was defined as a conversion of:
   a) an occluded vessel to a simple obstruction
   b) an occluded vessel to a partial thrombotic block
   c) an occluded vessel to a patent vessel
   d) intraluminal filling defect

6. Thrombolysis was represented by and measurable with the defect index if there was at least a:
   a) ≥20% increase
   b) ≥40% reduction
   c) ≤20% reduction
   d) none of the above

7. Of 8 patients with nontransmural myocardial infarction, th number considered to have lysis of intracoronary thrombu was:
   a) 4 in response to nitroglycerin
   b) 5 in response to streptokinase
   c) 7 in response to nitroglycerin
   d) 7 in response to streptokinase

8. Of 9 patients with unstable angina, the number having positive anatomic response to:
   a) nitroglycerin, was 7
   b) streptokinase, was 7
   c) streptokinase, was 6
   d) streptokinase, was 4

9. In all instances, the changes were visible:
   a) to the patient
   b) under a microscope
   c) to the unaided eye
   d) none of the above

10. Measurements, providing quantitative documentation, es tablish that intracoronary thrombus does occur in som patients with:
    a) nontransmural myocardial infarction
    b) unstable angina
    c) both of the above diseases
    d) none of the above

11. Intermittent coronary spasms may be involved in nor transmural myocardial infarction and unstable angina be cause of:
    a) changes in patients with myocardial infarction
    b) absence of intracoronary thrombus
    c) changes in angina patients
    d) all the above

12. The specific clinical syndrome that results may be a functio of the:
    a) duration of obstruction
    b) size and extent of artery or branch involved
    c) available collateral circulation
    d) all the above

***This article appears on page 1 of this issue.**

INSTRUCTIONS TO AUTHORS

The Publisher reserves copyright and renewal on all published material, and such material may not be reproduced in any form without the written permission of the Publisher. Statements in articles are the responsibility of the authors. The Publisher assumes no liability for any material published in the *Journal.* All accepted manuscripts are subject to editing to aid understanding and conserve space.

ADDRESS MANUSCRIPTS TO: William C. Roberts, MD, Editor-in-Chief, THE AMERICAN JOURNAL OF CARDIOLOGY, 6935 Arlington Road, Suite 406, Bethesda, Maryland 20814. The *covering letter* should state precisely and concisely the significance and uniqueness of the work in the authors' view. The authors might delineate the extent of any concessions they are readily prepared to make: for example, the elimination of 1 or more figures or tables or a portion of the text to increase the likelihood of publication of their work in the *Journal.* Several names and addresses should be provided of nonlocal experts who, in the authors' view, could provide objective and informed reviews of their work. The suggested reviewers will be carefully considered along with other experts in the field. Additionally, the editor would listen if the authors provided the names of any investigators they consider unlikely to give nonbiased reviews of their work.

Submit 3 copies (1 original and 2 xerographic copies) of the entire manuscript including text, references, figures, legends, and tables. Study recent past issues of the *Journal* for format. Arrange the paper as follows: (1) title page consisting of the article's title, the names of the authors, and the institution from which the work originated, (2) a second title page including only the article's title, (3) summary, (4) text, (5) references, (6) acknowledgment, (7) figure legends, and (8) tables. Number all pages in the above sequence, beginning with the title page as 1, the summary as 2, and so on (leave the second title page unnumbered). Type on 22 × 28 cm (8.5 × 11 inch) paper, only on 1 side of each sheet, double-spaced (including references) with at least 25 mm (1 inch) margins.

The second title page, the one which omits the names of the authors and the institution, will permit the Editor-in-Chief the option of acquiring blinded or nonblinded reviews. References to the institution in the text or to the author's previous work in the Reference section must be deleted or written in a manner that prevents identification of the authors and the institution. Label figures with the manuscript title rather than the authors' names so that blinded reviews can be obtained. The authors may state which type of review they wish in the covering letter.

TITLE PAGE, SUMMARY, AND ABSTRACT: Include the first or middle and last names with other initials of all authors. Provide a short *running title* of 3 to 6 words. Insert at the bottom the name and address of the institution from which the work originated, and information about grant support if necessary. Add at the bottom the phrase "*Address for reprints:*" followed by full name and address with zip code. Limit the **summary** to 250 words. Also, submit an **abstract** of 150 words or less to be used in the Table of Contents. List 2 to 6 **key words** for subject indexing at the end of the summary.

STYLE: Use appropriate **subheadings** throughout the body of the text, such as in the Methods, Results, and Comments sections. **Abbreviations** are permitted, but no more than 2 or 3 per manuscript. Spell out the first time they appear in the text followed by the abbreviation in parentheses. Consult the *Uniform Requirements for Manuscripts Submitted to Biomedical Journals* published in the *Annals of Internal Medicine* June 1982; 96: 766–771, and also the *Stylebook/Editorial Manual of the American Medical Association* for current usage. Use generic names of drugs. Do not spell out any number, including those less than 10, except when used for opening a sentence.

REFERENCES: In references, list **all authors,** inclusive pages for all journal references, and specific page numbers for all book references as shown below. Avoid referencing abstracts if possible, but indicate by the abbreviation (*abstr*) when doing so. Do not use periods after authors' initials. Check *Index Medicus* or *Annals of Internal Medicine* (June 1982) as cited above for journal titles and abbreviations. Personal communications do not constitute references. In referring to a manuscript that has been submitted but not yet published, use the phrase "unpublished observations" in parentheses.

Journal: Vismara LA, Vera Z, Miller RR, Mason DT. Efficacy of disopyramide phosphate in the treatment of refractory ventricular tachycardia. Am J Cardiol 1977; 39:1027–1034.

Chapter in Book: Schiebler GL, Van Mierop LHS, Krovetz LJ. Diseases of the tricuspid valve. In: Moss AJ, Adams F, eds. Heart Disease in Infants, Children and Adolescents. Baltimore: Williams & Wilkins, 1968: 134–139.

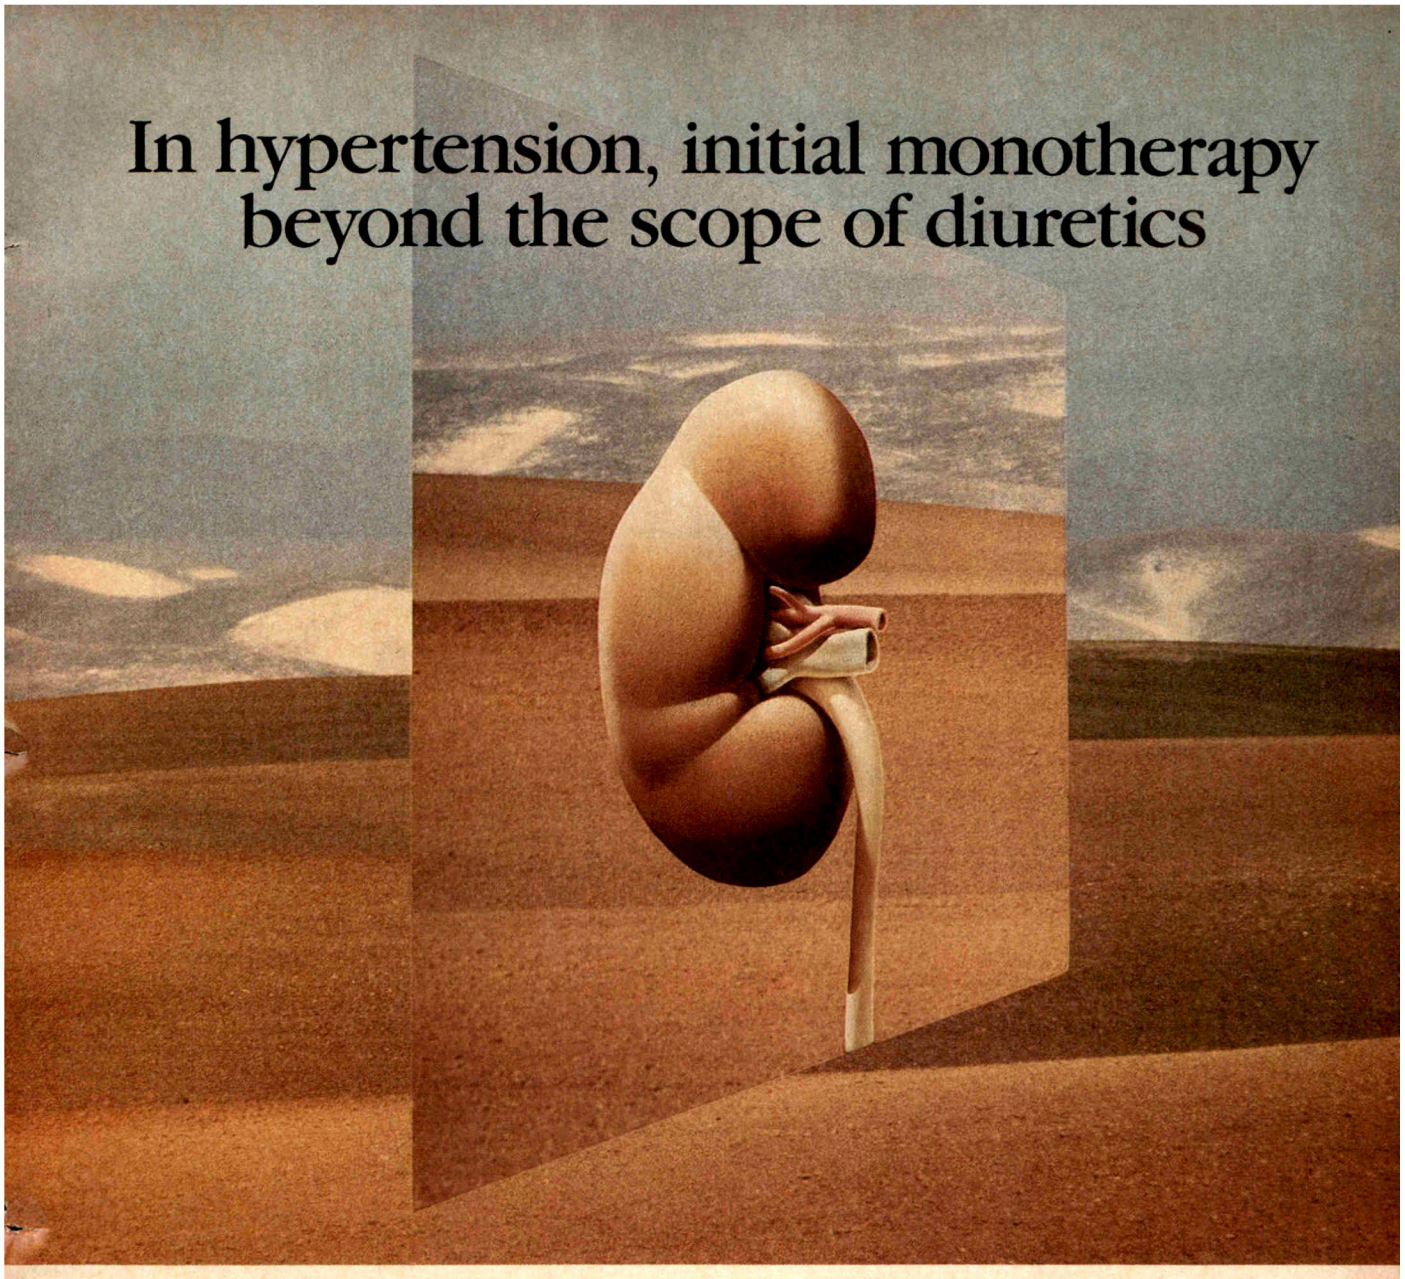
Book: Berne E. Principles of Group Treatment. New York: Oxford University Press, 1966:26.

FIGURES: Submit 3 glossy nonmounted *prints* of each photograph and drawing. Artwork of published articles will not be returned unless requested. Use black ink for all *charts* (line drawings). Make decimals, broken lines, etc. strong enough for reproduction. Use arrows to designate special features. Crop photographs to show only essential fields. Identify figures on back by number and title of the article (omit the authors' names so that blinded reviews can be obtained). Number figures in the order in which they are mentioned in the text. Indicate the top of each figure. Submit written permission from the publisher and author to reproduce any previously published figure. Limit figures to the number necessary to present the message clearly. Type each figure legend on a separate page, double-spaced. Identify at the end of each legend and in alphabetical order all abbreviations in the figure. The cost of color reproduction must be paid by the author. If color figures are submitted, identify in the covering letter who should be billed for the color charges.

TABLES: Place each table on a separate page, double-spaced. Number each table in Roman numerals (Table I, II, etc.) and title each table. Identify in alphabetical order at the bottom of the table all abbreviations used. When tabulating patients, use no more than 2 lines, preferably only 1 line, per patient. Use a plus sign (+) to indicate positive or present, a zero (0) for negative or absent, and a dash (—) for "no information available" or "not done."

REPRINTS: Price schedules and order cards for reprints will be mailed to the author on publication of the article. Individual reprints must be obtained through the author.

In hypertension, initial monotherapy beyond the scope of diuretics



As effective as hydrochlorothiazide without the drawbacks of a diuretic

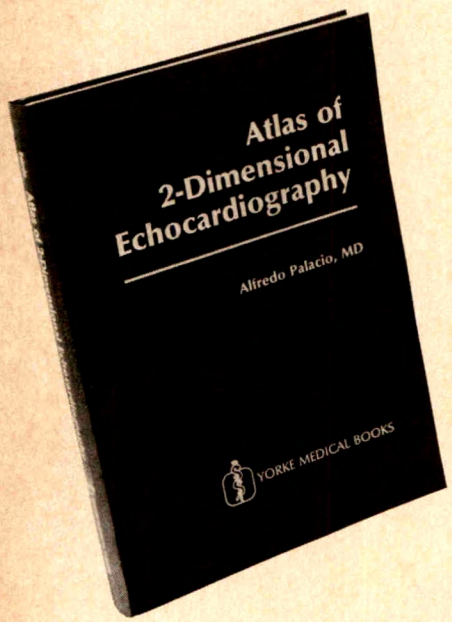
The First Practical Atlas of 2-D Echocardiography Ever Published



A "how-to-do-it" text/atlas presenting the broadest range of normal and abnormal 2-dimensional echocardiograms

Atlas of 2-Dimensional Echocardiography

by Alfredo Palacio, MD
Director of National Institute of Cardiology, Guayaquil, Ecuador
Foreword by David H. Spodick, MD, DSc
Professor of Medicine, University of Massachusetts Medical School;
Director, Division of Cardiology, St. Vincent Hospital, Worcester, Massachusetts

ISBN 0-914316-35-4, 198 pp, illus., large format 8¼ x 12, March '83, $65.00

2-dimensional echocardiography complemented by M-mode echocardiography has become one of the most common noninvasive diagnostic tools used by the cardiologist. With publication of the ATLAS OF 2-DIMENSIONAL ECHOCARDIOGRAPHY, neophyte and expert alike now have available to them the most truly usable didactic presentation of the subject ever published.

A true atlas, this book provides in a **large 8¼ x 12 format 251 black and white half tones, 152 line drawings and 6 charts** which illustrate in exacting detail how to perform and interpret 2-dimensional echocardiograms on patients with existing and/or suspected heart disease. The lucid accompanying text leads the reader step-by-step through the entire process, leaving little to the imagination. It presents in the most simple, direct way possible the broadest range of normal and abnormal 2-dimensional echocardiograms. The descriptions and detailed illustrations in its technical sections will ensure the superior level of performance of echocardiographic techniques that is a sine qua non for good results.

To order your copy of this important new book use the order form to the right.

Table of Contents

Foreword
Preface
Prologue
Introduction
EQUIPMENT
THE ECHOCARDIOGRAPHIC EXAMINATION
Parasternal position
  Longitudinal plane
  Transverse plane
Apical position
  Hemiaxial plane
  Axial plane
Subxiphoid position
  Transvascular plane
  Transcardiac plane
Suprasternal position
  Longitudinal plane
  Transverse plane
Final recommendations for the beginning technician
Special controls
Compendium of tomographic sections
DISEASES
Mitral stenosis
  Characteristics of the mitral stenosis in 2-dimensional echocardiography
  Longitudinal plane, long axis of the left ventricle
  Transverse plane, short axis
  Direction of future investigations
Mitral regurgitation
Tricuspid valve
Aortic valve and aortic root
Pulmonary valve
Intracardiac masses and tumors
Pericardial effusion
Ischemic heart disease
Congenital heart disease
Cardiomyopathies
Systemic arterial hypertension
MISCELLANEOUS
Valvular prostheses
Performance and volume of the left ventricle
Intracavitary cables and catheters

The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

Cardiology 1983

What is CARDIOLOGY 1983?

- A review of the year's newest and most important developments in cardiology
- A **multidisciplinary** approach to clinical and applied research
- A unique, cohesive summary of the state-of-the-art, written, not edited, by those making outstanding developments in the field
- A practical approach to a complicated and fast-moving subject designed to be read and used daily

Cardiology 1983 provides in a concise and readable format and style fundamental and new information essential to understanding the current thinking on managing cardiovascular disease. It coordinates what's new with well established data, arming the reader with a perspective on the field which is simply unavailable elsewhere. Its liberal use of illustrations and tables condenses valuable information into instantly understandable knowledge.

Who are the authors?

William C. Roberts, MD
Chief, Pathology Branch National Heart, Lung & Blood Institute National Institutes of Health Bethesda, Maryland, and Clinical Professor of Pathology and Medicine (Cardiology) Georgetown University, Washington, D.C.

Thomas P. Graham, Jr., MD
Professor of Pediatrics Chief, Division of Pediatric Cardiology Department of Pediatrics Vanderbilt University Vanderbilt Hospital Nashville, Tennessee

Robert B. Karp, MD
Professor of Surgery Department of Surgery University of Alabama Medical Center Birmingham, Alabama

Dean T. Mason, MD
Editor-in-Chief The American Heart Journal Director, Cardiac Center Cedars Medical Center Miami, Florida

- **Albert D. Pacifico, MD**
  Professor of Surgery Department of Surgery University of Alabama School of Medicine Birmingham, Alabama
- **Charles E. Rackley, MD**
  Professor and Chairman Department of Medicine Georgetown University Medical Center Washington, D.C.
- **James T. Willerson, MD**

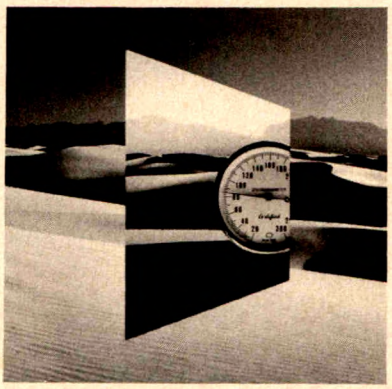
Wyeth

Another dimension in the management of hypertension



No electrolyte or metabolic risk factors
No long-term cardiovascular risk factors
No immunologic disturbances
No liver damage
No contraindications except hypersensitivity

Side effects are usually mild and transient

Patients may experience drowsiness and dry mouth early during WYTENSIN® (guanabenz acetate) therapy, but these subjective complaints are mostly mild and transient, especially when the initial dosage is *4 mg b.i.d.*, with the second dose at bedtime.

WyTensin®

(guanabenz acetate)

4mg b.i.d.

Brief Summary

Actions:
Wytensin® (guanabenz acetate) is an orally active central alpha-2 adrenergic agonist. Its antihypertensive action appears to be mediated via stimulation of central alpha adrenergic receptors, resulting in a decrease of sympathetic outflow from the brain at the bulbar level to the peripheral circulatory system. The acute antihypertensive effect of **Wytensin** occurs without major changes in peripheral resistance, but its chronic effect appears to be a decrease in peripheral resistance.

Indications and Usage:
Treatment of hypertension, alone or in combination with a thiazide diuretic.

Contraindication:
Known sensitivity to the drug.

Precautions:
1. Sedation: Causes sedation or drowsiness in a large fraction of patients. When used with centrally active depressants, e.g., phenothiazines, barbiturates and benzodiazepines, consider potential for additive sedative effects.

2. Patients with vascular insufficiency: Like other antihypertensives use with caution in severe coronary insufficiency, recent myocardial infarction, cerebrovascular disease, or severe hepatic or renal failure.

3. Rebound: Sudden cessation of therapy with central alpha agonists like **Wytensin** may rarely result in "overshoot" hypertension and more commonly produces increase in serum catecholamines and subjective symptomatology.

INFORMATION FOR PATIENTS:
Advise patients on **Wytensin** to exercise caution when operating dangerous machinery or motor vehicles until it is determined they do not become drowsy or dizzy. Warn patients that tolerance for alcohol and other CNS depressants may be diminished. Advise patients not to discontinue therapy abruptly.

LAB TESTS:
In clinical trials, no clinically significant lab test abnormalities were identified during acute or chronic therapy. Tests included CBC, urinalysis, electrolytes, SGOT, bilirubin, alkaline phosphatase, uric acid, BUN, creatinine, glucose, calcium, phosphorus, total protein, and Coombs' test. During long-term use there was small decrease in serum cholesterol and total triglycerides without change in high-density lipoprotein fraction. In rare instances occasional nonprogressive increase in liver enzymes was observed, but no clinical evidence of hepatic disease.

DRUG INTERACTIONS:
Wytensin® was not demonstrated to cause drug interactions when given with other drugs, e.g., digitalis, diuretics, analgesics, anxiolytics, and antiinflammatory or antiinfective agents, in clinical trials. However, potential for increased sedation when given concomitantly with CNS depressants should be noted.

DRUG/LAB TEST INTERACTIONS:
No lab test abnormalities were identified with **Wytensin** use.

CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY:
No evidence of carcinogenic potential emerged in rats during a two-year oral study with **Wytensin** at up to 9.5 mg/kg/day, i.e., about 10 times maximum recommended human dose. In the Salmonella microsome mutagenicity (Ames) test system, **Wytensin** at 200-500 mcg per plate or at 30-50 mcg/ml in suspension gave dose-related increases in number of mutants in one (TA 1537) of five *Salmonella typhimurium* strains with or without inclusion of rat liver microsomes. No mutagenic activity was seen at doses up to those which inhibit growth in the eukaryotic microorganism, *Schizosaccharomyces pombe*, or in Chinese hamster ovary cells at doses up to those lethal to the cells in culture. In another eukaryotic system, *Saccharomyces cerevisiae*, **Wytensin** produced no activity in an assay measuring induction of repairable DNA damage. Reproductive studies showed a decreased pregnancy rate in rats given high oral doses (9.6 mg/kg), suggesting impairment of fertility. Fertility of treated males (9.6 mg/kg) may also have been affected, as suggested by decreased pregnancy rate of mates, even though females received drug only during last third of pregnancy.

PREGNANCY:
Pregnancy Category C:
WYTENSIN® MAY HAVE ADVERSE EFFECTS ON FETUS WHEN ADMINISTERED TO PREGNANT WOMEN. A teratology study in mice indicated possible increase in skeletal abnormalities when **Wytensin** is given orally at doses 3 to 6 times maximum recommended human dose of 1.0 mg/kg. These abnormalities, principally costal and vertebral, were not noted in similar studies in rats and rabbits. However, increased fetal loss has been observed after oral **Wytensin** given to pregnant rats (14 mg/kg) and rabbits (20 mg/kg). Reproductive studies in rats have shown slightly decreased live-birth-indices, decreased fetal survival rate, and decreased pup body weight at oral doses of 6.4 and 9.6 mg/kg. There are no adequate, well-controlled studies in pregnant women. **Wytensin®** should be used during pregnancy only if potential benefit justifies potential risk to fetus.

NURSING MOTHERS:
Because no information is available on **Wytensin** excretion in human milk, it should not be given to nursing mothers.

PEDIATRIC USE:
Safety and effectiveness in children less than 12 years of age have not been demonstrated; use in this age group cannot be recommended.

Adverse Reactions:
Incidence of adverse effects was ascertained from controlled clinical studies in U.S. and is based on data from 859 patients on **Wytensin** for up to 3 years. There is some evidence that side effects are dose-related.

Following table shows incidence of adverse effects in at least 5% of patients in study comparing **Wytensin** to placebo, at starting dose of 8 mg b.i.d.

Adverse Effect	Placebo (%) n = 102	Wytensin (%) n = 109
Dry mouth	7	28
Drowsiness or sedation	12	39
Dizziness	7	17
Weakness	7	10
Headache	6	5

In other controlled clinical trials at starting dose of 16 mg/day in 476 patients, incidence of dry mouth was slightly higher (38%) and dizziness was slightly lower (12%), but incidence of most frequent adverse effects was similar to placebo-controlled trial. Although these side effects were not serious, they led to discontinuation of treatment about 15% of the time. In more recent studies using an initial dose of 8 mg/day in 274 patients, incidence of drowsiness or sedation was lower, about 20%.

Other adverse effects reported during clinical trials but not clearly distinguishable from placebo effects and occurring with frequency of 3% or less: Cardiovascular—chest pain, edema, arrhythmias, palpitations. Gastrointestinal—nausea, epigastric pain, diarrhea, vomiting, constipation, abdominal discomfort. Central nervous system—anxiety, ataxia, depression, sleep disturbances. ENT disorders—nasal congestion. Eye disorders—blurring of vision. Musculoskeletal—aches in extremities, muscle aches. Respiratory—dyspnea. Dermatologic—rash, pruritus. Urogenital—urinary frequency, disturbances of sexual function. Other—gynecomastia, taste disorders.

Drug Abuse and Dependence:
No dependence or abuse has been reported.

Overdosage:
Accidental ingestion caused hypotension, somnolence, lethargy, irritability, miosis, and bradycardia in two children aged one and three years. Gastric lavage and pressor substances, fluids, and oral activated charcoal resulted in complete and uneventful recovery within 12 hours in both. Since experience with accidental overdosage is limited, suggested treatment is mainly supportive while drug is being eliminated and until patient is no longer symptomatic. Vital signs and fluid balance should be carefully monitored. Adequate airway should be maintained and, if indicated, assisted respiration instituted. No data are available on **Wytensin** dialyzability.

Dosage and Administration:
Individualize dosage. A starting dose of 4 mg b.i.d. is recommended, whether used alone or with a thiazide diuretic. Dosage may be increased in increments of 4 to 8 mg/day every one to two weeks, depending on response. Maximum dose studied has been 32 mg b.i.d., but doses this high are rarely needed.

How Supplied:
Wytensin® (guanabenz acetate) Tablets, 4 mg and 8 mg, bottles of 100.

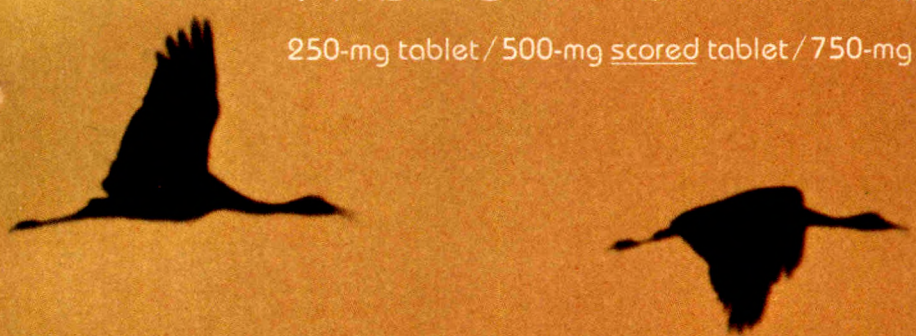
SUSTAINED RELEASE

Procan® SR

(PROCAINAMIDE HYDROCHLORIDE TABLETS)

250-mg tablet / 500-mg scored tablet / 750-mg scored tablet



Enhances the value of oral procainamide for selected cardiac dysrhythmias

With modern sustained-release Procan SR, short duration of effect no longer impedes the usefulness of procainamide for maintenance therapy. A standard medication now assumes greater importance, both in terms of convenience and patient compliance.

Administered half as often as conventional oral procainamide

Wide versatility in cardiac conditions

Can be used concomitantly with digoxin

Ideal maintenance therapy

If in the past you have substituted another medication for maintenance therapy because of compliance problems with conventional oral procainamide, now you can logically turn to the modern oral procainamide.

Procan SR... the original sustained-release oral procainamide

PARKE-DAVIS
Division of Warner-Lambert Company
Morris Plains, New Jersey 07950

Please see next page for brief summary of prescribing information.

Procan® SR
(procainamide hydrochloride tablets)
SUSTAINED RELEASE

Before prescribing, please see full prescribing information.
A Brief Summary follows.

The prolonged administration of procainamide often leads to the development of a positive antinuclear antibody (ANA) test with or without symptoms of lupus erythematosus-like syndrome. If a positive ANA titer develops, the benefit/risk ratio related to continued procainamide therapy should be assessed. This may necessitate consideration of alternative antiarrhythmic therapy.

INDICATIONS AND USAGE: Oral procainamide is indicated in the treatment of premature ventricular contractions and ventricular tachycardia, atrial fibrillation, and paroxysmal atrial tachycardia.

CONTRAINDICATIONS: It has been suggested that procainamide be contraindicated in patients with myasthenia gravis. Hypersensitivity to the drug is an absolute contraindication; in this connection, cross-sensitivity to procaine and related drugs must be borne in mind. Procainamide should not be administered to patients with complete atrioventricular heart block. Procainamide is also contraindicated in cases of second-degree and third-degree A-V block unless an electrical pacemaker is operative.

PRECAUTIONS: General —During administration of the drug, evidence of untoward myocardial responses should be carefully watched for in all patients. In the presence of an abnormal myocardium, procainamide may at times produce untoward responses. In atrial fibrillation or flutter, the ventricular rate may increase suddenly as the atrial rate is slowed. Adequate digitalization reduces, but does not abolish, this danger. If myocardial damage exists, ventricular tachysystole is particularly hazardous. Correction of atrial fibrillation, with resultant forceful contractions of the atrium, may cause a dislodgement of mural thrombi and produce an embolic episode. However, it has been suggested that in a patient who is already discharging emboli, procainamide is more likely to stop than to aggravate the process.

Attempts to adjust the heart rate in a patient who has developed ventricular tachycardia during an occlusive coronary episode should be carried out with extreme caution. Caution is also required in marked disturbances of atrioventricular conduction such as A-V block, bundle branch block, or severe digitalis intoxication, where the use of procainamide may result in additional depression of conduction and ventricular asystole or fibrillation.

Because patients with severe organic heart disease and ventricular tachycardia may also have complete heart block, which is difficult to diagnose under these circumstances, this complication should always be kept in mind when treating ventricular arrhythmias with procainamide. If the ventricular rate is significantly slowed by procainamide without attainment of regular atrioventricular conduction, the drug should be stopped and the patient reevaluated since asystole may result under these circumstances.

In patients receiving normal dosage, but who have both liver and kidney disease, symptoms of overdosage (principally ventricular tachycardia and severe hypotension) may occur due to drug accumulation.

Instances of a syndrome resembling lupus erythematosus have been reported in connection with maintenance procainamide therapy. The mechanism of this syndrome is uncertain. Polyarthralgia, arthritis, and pleuritic pain are common symptoms; to a lesser extent, fever, myalgia, skin lesions, pleural effusion, and pericarditis may occur. Rare cases of thrombocytopenia or Coombs-positive hemolytic anemia have been reported which may be related to this syndrome.

Laboratory Tests—Patients receiving procainamide for extended periods of time, or in whom symptoms suggestive of a lupus-like reaction appear, should have antinuclear antibody titers measured at regular intervals. The drug should be discontinued if there is a rising titer (antinuclear antibody) or clinical symptoms of LE appear. The LE syndrome may be reversible upon discontinuation of the drug. If discontinuation of the drug does not cause remission of the symptoms, steroid therapy may be effective. If the syndrome develops in a patient with recurrent life-threatening arrhythmias not controllable by other antiarrhythmic agents, steroid suppressive therapy may be used concomitantly with procainamide. It is recommended that tests for lupus erythematosus be carried out at regular intervals in patients receiving maintenance procainamide therapy.

Routine blood counts are advisable during maintenance procainamide therapy.

ADVERSE REACTIONS: Agranulocytosis has occasionally followed the repeated use of the drug, and deaths have occurred. Therefore, routine blood counts are advisable during maintenance procainamide therapy. The patient should be instructed to report any soreness of the mouth, throat, or gums, unexplained fever, or any symptoms of upper respiratory tract infection. If any of these should occur, and leukocyte counts indicate cellular depression, procainamide therapy should be discontinued and appropriate treatment should be instituted immediately.

Hypersensitivity reactions, such as angioneurotic edema and maculopapular rash have also occurred.

A syndrome resembling lupus erythematosus has been reported (see PRECAUTIONS).

Hypotension following oral administration is rare.

Large oral doses of procainamide may sometimes produce anorexia, nausea, urticaria, and/or pruritus.

Reactions consisting of fever and chills have also been reported, including a case with fever and chills plus nausea, vomiting, abdominal pain, acute hepatomegaly, and a rise in serum glutamic oxaloacetic transaminase following single doses of the drug. Bitter taste, diarrhea, weakness, mental depression, giddiness, and psychosis with hallucinations have been reported. The possibility of such untoward effects should be borne in mind.

DOSAGE AND ADMINISTRATION: Procan SR (procainamide hydrochloride) tablets are a sustained-release product form. The duration of action of procainamide hydrochloride supplied in this sustained-release product form allows dosing at intervals of every six hours instead of the more frequent every-three-hour dosing interval required for standard preparations of oral procainamide hydrochloride. The convenient six-hour dosing schedule may encourage patient compliance.

Ventricular tachycardia—Treatment with standard procainamide hydrochloride is recommended until the tachycardia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows: An initial dose of 1 g of standard procainamide hydrochloride followed thereafter by a total daily dose of 50 mg/kg of body weight given at three hour intervals. The suggested oral dosage for premature ventricular contractions is 50 mg/kg of body weight daily given in divided doses at three-hour intervals.

The suggested maintenance dosage of Procan SR is 50 mg/kg of body weight daily given in divided doses at six-hour intervals.

Although the dosage for each patient must be determined on an individual basis, the following may be used as a guide for providing the total daily dosage: patients weighing less than 55 kg (120 lb), 0.5 g every six hours; patients weighing between 55 and 91 kg (120 and 200 lb), 0.75 g every six hours; and patients weighing over 91 kg (200 lb), 1 g every six hours.

Atrial fibrillation and paroxysmal atrial tachycardia—Treatment with standard procainamide hydrochloride is recommended until the arrhythmia is interrupted or the limit of tolerance is reached. Maintenance may then be continued with Procan SR.

The suggested dosage is as follows. An initial dose of 1.25 g of standard procainamide hydrochloride may be followed in one hour by 0.75 g if there have been no electrocardiographic changes. Standard procainamide hydrochloride may then be given at a dose of 0.5 to 1 g every two hours until interruption of the arrhythmia or the tolerance limit is reached.

The suggested maintenance dosage for Procan SR is 1 g every six hours.

If procainamide therapy is continued for appreciable periods, electrocardiograms should be made occasionally to determine the need for the drug.

HOW SUPPLIED: Procan SR 250 mg (green, film-coated tablet. P-D 202) is available in bottles of 100 (N 0071-0202-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0202-40). Each sustained-release tablet contains 250 mg procainamide hydrochloride.

Procan SR 500 mg (yellow, scored, film-coated tablet. P-D 204) is available in bottles of 100 (N 0071-0204-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0204-40). Each sustained-release tablet contains 500 mg procainamide hydrochloride.

Procan SR 750 mg (orange, scored, film-coated tablet. P-D 205) is available in bottles of 100 (N 0071-0205-24) and in unit-dose packages of 100 (10 strips of 10 tablets each) (N 0071-0205-40). Each sustained-release tablet contains 750 mg procainamide hydrochloride.

Storage—Protect from moisture. Store bottles below 86° F (30° C). Store unit-dose packages at controlled room temperature, 59°-86° F (15°-30° C).

Prolongation of the Q-T Interval in Man During Sleep

KEVIN F. BROWNE, MD, ERIC PRYSTOWSKY, MD, JAMES J. HEGER, MD, DONALD A. CHILSON, MD, and DOUGLAS P. ZIPES, MD

Parasympathetic blockade shortens the duration of the Q-T interval and ventricular effective refractory period independent of heart rate change. Since relative parasympathetic effect increases during sleep, it was determined whether sleep was associated with a change in the Q-T interval. Fifteen patients receiving no drugs underwent 3 to 6 days of continuous electrocardiographic recordings. Tracings were sampled every 30 minutes and recorded at a paper speed of 25 mm/s. This provided 12,000 Q-T and R-R intervals that were measured. Comparison of R-R intervals that had similar durations during sleep and awake states revealed that the duration of the Q-T interval was longer during sleep in all 15 patients ($p < 0.001$). Eight patients had sufficient range of overlap of R-R intervals to compare linear regression lines of Q-T intervals recorded while awake with Q-T intervals recorded while asleep. The regression lines during sleep exhibited a mean intercept change of 38 ± 37 ms and mean slope change of −0.021 ± 0.040 ms when compared with the regression lines during the awake state. The difference in Q-T interval between awake and sleep states was 19 ± 7 ms when calculated at a heart rate of 60 beats/min. These statistical comparisons of the relationship of the Q-T interval to R-R interval indicate that the Q-T interval is longer during sleep than during the awake state at the same heart rate. Prolongation of the Q-T interval during sleep may reflect increased vagal tone or sympathetic withdrawal. These changes in repolarization may be related to the diurnal variation of some ventricular arrhythmias.

Abnormal myocardial repolarization has been linked to the development of malignant arrhythmias in patients with the prolonged Q-T interval syndrome[1–3] and in patients after acute myocardial infarction.[4,5] It is clear that heart rate, drugs, electrolytes, and autonomic tone influence the Q-T interval. In previous investigations, drugs to block 1 or both limbs of the autonomic nervous system have been administered, with either rate correction formulas[6–8] or atrial pacing[9,10] used to eliminate effects of heart rate changes. However, we were unable to find any information on the effect of heightened parasympathetic tone on Q-T interval duration in man.

Sleep represents a naturally occurring period of increased parasympathetic tone or sympathetic tone withdrawal[11,12] and may prolong the Q-T interval independently of the slowing of heart rate. This prolongation may play an important role in the decrease in ventricular ectopy noted in some patients during sleep.[13,14] Since a significant slowing of heart rate reflecting the relatively increased parasympathetic tone occurs during sleep,[12] this change alone may prolong the Q-T interval and mask any direct autonomic effect. To permit analysis of the effect of an intervention such as sleep on the Q-T interval, we developed a new method of evaluating the measured Q-T interval duration which is independent of heart rate effects. The purpose of this study was to test the hypothesis that the duration of the Q-T interval in man is prolonged during sleep.

Methods

Fifteen subjects underwent 72 to 144 hours of continuous electrocardiographic recording. All patients met the following entrance criteria: (1) no evidence of heart disease by history, physical examination, or resting electrocardiography; (2) no medications; (3) <600 premature atrial or ventricular complexes per 24 hours; (4) P-R interval during normal sinus rhythm <0.20 second; (5) QRS duration <0.10 second; and (6) corrected Q-T interval (Bazett's formula) <0.44 second. Nine

subjects had 6 and 6 subjects had three 24-hour continuous electrocardiographic recordings. Tracings approximately 7.5 seconds in duration (Fig. 1) were printed out at 25 mm/s paper speed every 30 minutes. In all, 3,400 tracings were analyzed.

Data measurement: The duration of the Q-T interval was measured using a digitizing board (HP9874A) interfaced with the Hewlett-Packard 9826 computer. Four to 8 complexes were measured from each tracing. A tracing was excluded if an ectopic complex occurred during the 7.5-second interval or if any single R-R interval varied by more than 10% of the mean R-R interval. The mean R-R and Q-T intervals were computed for each tracing from the arithmetic mean of 4 to 8 consecutive complexes and logged along with the time of day and activity (Fig. 1). The duration of each Q-T interval was measured from the beginning of the Q wave to the end of the T wave. The end of the T wave was determined by drawing a tangent to the steepest portion of the downsloping T wave. The point where the tangent intersects with the isoelectric line was used as termination of the T wave (Fig. 1).

Each hour of continuous electrocardiographic recording was coded for either awake or sleep state as determined by examining the subject's diary. A transition period was defined as the 1-hour interval after the listed bedtime and the 1-hour interval before waking time. All values from the transition period were not used in the analysis.

Consistent with a previous report[15] in 2 patients, the Q-T interval recorded while the patient was standing and supine at the same heart rate did not change.

Definitions: Tracing: one 7.5-second print-out from a continuous electrocardiographic recording. Measured Q-T and R-R interval: that interval measured directly from the arithmetic mean of 4 to 8 consecutive complexes found on one 7.5-second tracing. Calculated Q-T interval: the value of the Q-T interval obtained by solving a linear regression formula for a given R-R interval. Corrected Q-T interval: the value of the Q-T interval obtained by solving Bazett's formula for a given R-R interval.

Statistical analysis: Two-way analysis of variance[16] was performed on the Q-T interval duration with the R-R interval and sleep state as independent variables. Because the awake data were skewed toward short R-R cycle lengths and sleep data were skewed to longer cycle lengths, analysis of covariance was performed on the Q-T interval with sleep state as the independent variable and R-R interval as the covariate. In addition, a plot of Q-T versus R-R interval was made for each patient. An R-R interval range was chosen so that the number of data points for awake and sleep states present in each R-R interval increment (cell size) would be relatively uniform for each patient. A linear regression line was constructed using least squares analysis[16] for sleep and awake states for each patient (Fig. 2) and for all patients taken together. Comparison of the regression lines was performed using residual mean squares test.[16] Q-T intervals were corrected for heart rate using Bazett's formula, that is, $Q\text{-}Tc = Q\text{-}T/\sqrt{R\text{-}R \text{ interval}}$. The Q-Tc intervals for awake versus sleep states were then compared using one-way analysis of variance[16] for each patient and then as a group.

Results

Eleven men and 4 women with a mean age of 44 years were enrolled in the study. There were 3,400 tracings (Fig. 1) analyzed from the continuous electrocardiographic recordings, of which 2,020 met the measurement criteria representing over 12,000 measured R-R and Q-T intervals.

Analysis of variance: The data for each patient were plotted as shown in Figure 2. An R-R interval range was chosen to permit uniform cell size for each patient. Application of 2-way analysis of variance with R-R cycle length and sleep state as independent variables revealed that the Q-T interval was longer during the sleep state compared with the awake state in all 15 patients (<0.001). The mean R-R cycle length prolonged during sleep state in all patients (760 ± 120 ms to 920 ± 140

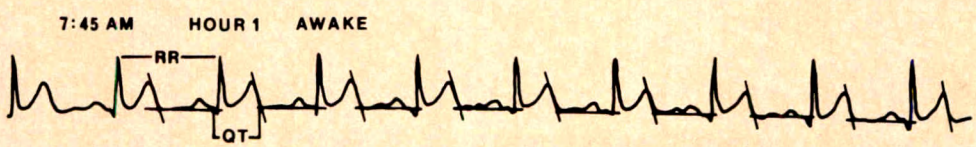

FIGURE 1. A typical tracing obtained from 1 channel of the continuous electrocardiographic recording. R-R intervals were measured from the peaks of the R waves, and the duration of the Q-T interval was measured from the onset of the QRS complex to the termination of the T wave. A tangent to the steepest portion of the downsloping T wave was constructed, and the intersection of the tangent and isoelectric line was defined as the T-wave termination.

TABLE II Comparison of Overall Awake and Asleep Regression Lines

State	Q-T Intervals (n)	Slope	Intercept	Heart Rate Range (beats/min)
Awake	1,138	0.130	277	57 to 86
Asleep	682	0.102	325	57 to 86
Simonson[23] formula	960	0.140	255*	56 to 83

* Calculated at an age of 44 years (242 + 0.3 × age).

ms). Grouping all 15 patients and performing the same analysis over an R-R interval range of 700 to 1,050 ms again showed that the Q-T interval prolonged during sleep compared with the awake state, independent of the R-R cycle length ($p < 0.001$).

Analysis of covariance: Because longer R-R cycle lengths occurred during sleep and shorter R-R cycle lengths occurred during the awake state, analysis of covariance was performed on the Q-T interval with R-R intervals covarying for each patient. Fourteen of 15 patients had significant prolongation of the Q-T interval ($p < 0.003$) during the sleep state compared with the awake state.

Linear regression analysis (Q-T = A + B × R-R interval): In 8 patients, sufficient overlap of sleep versus awake R-R intervals existed to permit construction of linear regression lines for each state over the same R-R cycle lengths. The R-R interval range, slope (B), and intercept (A) values of awake and sleep state are listed in Table I. All 8 patients had significantly different linear regression lines during sleep when compared with awake data ($p < 0.001$). In addition, the regression lines for awake state and sleep state were significantly different from the linear regression lines developed for the awake plus sleep data ($p < 0.01$). Using the regression lines in Table I, the calculated Q-T intervals for awake versus asleep state at an R-R interval of 1,000 ms were compared. The calculated Q-T interval prolonged by 19 ± 7 ms during sleep for these patients.

All patients were grouped and linear regression lines were developed for the awake and asleep state over an R-R cycle length of 700 to 1,050 ms. Table II lists the number of Q-T intervals, slope, and intercept for each state. The linear regression line developed for the awake state is similar to the linear formula of Simonson (Table II). The calculated Q-T interval prolonged 20 ms during sleep as compared with the awake state at an R-R cycle length of 1,000 ms.

Correction of the Q-T interval by Bazett's formula: The corrected Q-T interval (Q-Tc) using Bazett's formula was significantly longer in 7 of 15 patients ($p < 0.01$) during sleep than awake states when comparing all data from each patient. Two patients' Q-Tc intervals significantly shortened during sleep ($p < 0.01$) and 6 patients had no change. When the data were limited to cycle lengths compared during 2-way analysis of variance, Q-Tc was significantly longer ($p < 0.01$) during sleep in 14 of 15 patients. Pooling all 15 patients and comparing data over an R-R interval range from 700 to 1,050 ms, the Q-Tc was 424 ± 29 ms while awake and 437 ± 25 ms during sleep ($p < 0.01$). The change in the corrected Q-T interval during sleep predicted by Bazett's formula is not significantly different from the prolongation found by developing regression lines for each patient.

Discussion

Our data demonstrate that the Q-T interval prolongs during sleep independently of the change in R-R interval. The cause of this prolongation may be a change in the balance of the 2 limbs of the autonomic nervous system. It has been shown previously that during atrial pacing, loss of parasympathetic tone produced by atropine shortens the Q-T interval[10] and loss of sympathetic tone produced by propranolol either has no effect on[10] or may slightly prolong[9,10] the Q-T interval independently of change in R-R cycle length. Since all patients had sinus slowing during sleep, it may be inferred

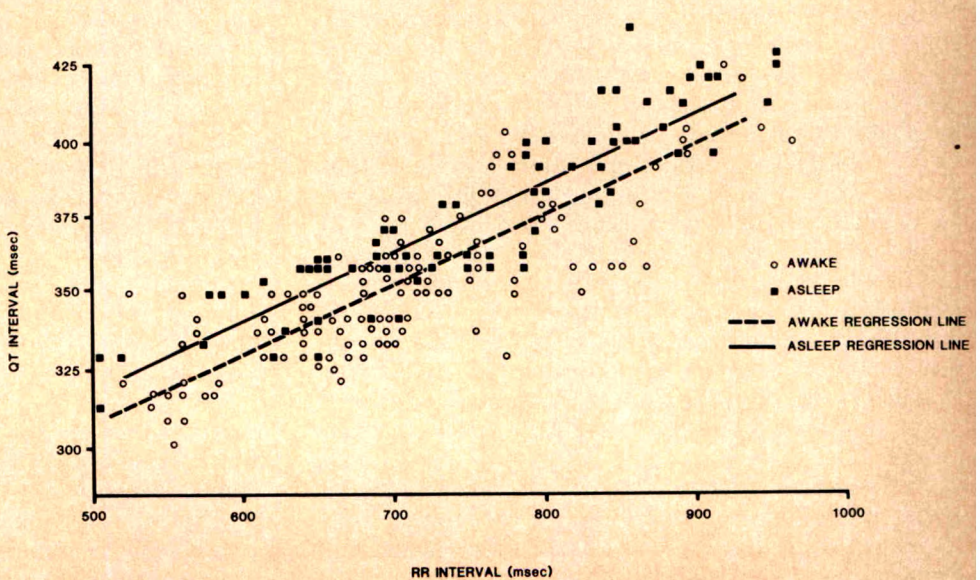

FIGURE 2. All Q-T intervals for 1 patient measured over an R-R interval range of 500 to 1,000 ms are plotted. Regression lines for awake and asleep data were constructed using least mean squares analysis.[16]

that either sympathetic withdrawal or increased parasympathetic tone or both occur during sleep. Experiments in cats have shown that slowing of heart rate during sleep is due mainly to sympathetic withdrawal.[12] Regardless of which limb of the autonomic nervous system is changing during sleep, the net result is increased parasympathetic effect. This change in autonomic balance may be responsible in part for the prolongation of the Q-T interval we have demonstrated to occur during sleep.

Other variables also may contribute to the change in the Q-T interval found in this study. The state of sleep has been shown to change relative autonomic tone.[12] During rapid eye movement sleep, there is an increase in sympathetic tone which may shorten the Q-T interval independently of heart rate change. Although we did not monitor rapid eye movement sleep, if it occurred it would have biased the sleep data to show less Q-T interval prolongation than may be present during non-rapid eye movement sleep.

The Q-T interval during the awake state may have been influenced by physical activity, meals, and activities such as smoking. Physical activity has been shown to shorten the Q-T interval but only at heart rates that would have been excluded from analysis in this study because of no comparable heart rate during sleep. Position, that is, supine compared with sitting or standing, may have influenced the results. However, it has been reported[15] that position had no effect on the Q-T interval and we found no difference in Q-T interval related to position in 2 patients.

Meals and other activities may shorten or prolong the Q-T interval an unknown amount. The data collected during these periods would comprise only a minor portion of the awake state data for any patient.

Factors other than the autonomic nervous system, such as serum potassium, calcium, pH, and body temperature, may influence sinoatrial nodal automaticity and the Q-T interval, and may vary during the sleep and awake states. It is difficult to determine the relative influence of all these factors on sinus cycle length and Q-T interval at a particular time of day or night. To complicate matters further, even at the same time of the day, the parasympathetic and sympathetic nervous system modulate sinus nodal, atrioventricular nodal, and ventricular function to different degrees.[17] This study was not designed to elucidate the mechanism for Q-T prolongation and our postulate, therefore, that prolongation of the Q-T interval at night is due mainly to heightened vagal tone remains speculative.

We[10] previously demonstrated that use of Bazett's formula to correct Q-T interval for heart rate may be invalid during changes in autonomic tone because the autonomic nervous system has both direct and heart rate-related effects on the Q-T interval. To avoid this potential error, we compared Q-T intervals measured at similar sinus cycle lengths during sleep with the awake state.

Different Q-T intervals during the awake and asleep states at similar R-R intervals can be explained by several possibilities. First, the same sinus rate at different times during a 24-hour cycle, for example while awake and asleep, does not necessarily mean the same degree of autonomic balance at each of those times. The autonomic balance affecting the sinoatrial node may remain unchanged, so the heart rate is the same, at a time when cholinergic effects on the ventricle were selectively and regionally increased or adrenergic effects decreased. Since the right stellate ganglion exerts a predominant effect on sinus rate, one could postulate constant vagal and right stellate ganglion tone (and therefore the same heart rate) associated with an increase in left stellate ganglion tone (and therefore Q-T prolongation[18]).

If similar R-R intervals while awake and asleep do indicate that the autonomic *balance* (that is, net effect) at the sinoatrial node is similar for both states, the *absolute* level of either parasympathetic or sympathetic stimulation may be different, but their net effect on the sinus node may remain unchanged. For example, during the awake state both sympathetic and parasympathetic tone may be high and during the asleep state both may be low. The net effect of the overall autonomic tone on automaticity of sinus pacemaker cells may be the same, but the effect on repolarization of ventricular muscle cells may be different. High overall autonomic tone may shorten the Q-T interval compared with low overall autonomic tone because the effects of elevated adrenergic tone may predominant over the effects of elevated cholinergic tone on ventricular repolarization. Low overall autonomic tone may result in the same *net* effect on the sinus node as high overall autonomic tone, hence the same heart rate; but during periods of low autonomic tone cholinergic effects may predominate over adrenergic effects on ventricular repolarization[19] and prolong the Q-T interval. These comments are naturally speculative and need to be tested in appropriate animal models.

The method of analysis used in this study can be applied to determine the effect that any intervention has on the duration of the Q-T interval independently of heart rate provided there is an overlap of the sinus rates before and after the intervention. For example, prolongation of the Q-T interval induced by antiarrhythmic drugs could be qualitatively and quantitatively assessed. To evaluate the effect on Q-T interval of an intervention, determination of the change in Q-T interval at multiple heart rates may give a more accurate assessment of the potential influence of heart rate. This may be important when evaluating antiarrhythmic drugs which show use dependency, that is, different effects on the action potential at different heart rates.[20] Rate correction formulas would permit comparison of Q-T intervals only at 1 corrected heart rate. Developing regression formulas allows comparison of the effect of an intervention at more than 1 heart rate. For example, sleep prolongs the Q-T interval 16, 22, and 24 ms at heart rates of 60, 70, and 80 beats/min, respectively.

Bazett's formula correctly predicted the direction of magnitude of change of the Q-T interval during sleep for the 8 patients in Table I over the listed R-R interval range. Using a wider R-R interval range of 700 to 1,050 ms, Bazett's formula predicted Q-T interval prolongation for all 15 patients as a group. By including for analysis only R-R cycle lengths in the range of 700 to 1,050 ms, correction for heart rate by Bazett's formula

was relatively accurate compared with our linear regression model in this study. Error was introduced into the formula when either faster or slower rates were corrected. It has been shown that when both Q-T interval and heart rate have large changes after an intervention, Bazett's formula may be misleading when predicting the change in Q-T interval caused by a specific intervention.[10] For those interventions in which regression analysis of the Q-T interval change compares favorably with the change found using a heart rate correction formula, it seems reasonable to apply the formula.

Sleep has been shown to be an important antiarrhythmic factor in some patients[13,21] and awakening has been related to development of arrhythmias.[22] These observations suggest that a neural mechanism operative during sleep may be responsible for the decrease in arrhythmia. In some of these patients, the decrease in arrhythmia was greater during sleep than during treatment with various antiarrhythmic drugs.[13] In our study, although the prolongation of the Q-T interval demonstrated during sleep is small, this change in the recovery of ventricular excitability may be related to the emergence or suppression of ventricular arrhythmias in some patients.

Relation of Mode of Induction and Cycle Length of Ventricular Tachycardia: Analysis of 104 Patients

JOHN U. DOHERTY, MD, MICHAEL G. KIENZLE, MD, HARVEY L. WAXMAN, MD, ALFRED E. BUXTON, MD, FRANCIS E. MARCHLINSKI, MD, and MARK E. JOSEPHSON, MD

One hundred four consecutive patients with ventricular tachycardia (VT) were examined to correlate the cycle length with the mode of initiation of VT (single, double, and triple extrastimuli and rapid pacing). Tachycardias induced with a single extrastimulus were slower (342 ± 72 ms, mean cycle length) than those induced with double (295 ± 60 ms) or triple (282 ± 56 ms) extrastimuli or rapid pacing (293 ± 40 ms). There were no differences among the last 3 groups. In 38 patients who had endocardial catheter mapping to determine the site of origin of VT, distance from stimulation site to the site of origin was estimated and correlated with mode of initiation. There was no difference in mode of initiation when the stimulation site was close (<3 cm), intermediate (3 to 5 cm), or distant (>8 cm) from the site of origin. To address the issue of distance from stimulation site to the site of origin somewhat differently, mode of initiation was correlated with site of previous myocardial infarction in 69 patients with VT initiated from the right ventricular apex. Again, mode of initiation did not differ among patients with septal, inferior, lateral, or multiple myocardial infarctions. Thus, cycle length of VT initiated with a single extrastimulus was slower than that initiated with double or triple extrastimuli or rapid pacing and the mode of initiation of VT was unrelated to site of myocardial infarction or distance between stimulation site and site of origin of VT.

Programmed electrical stimulation has been found to be a specific and sensitive technique for the diagnosis and therapy of patients with ventricular tachycardia (VT).[1–7] Although right ventricular stimulation can induce VT in most instances, left ventricular stimulation is occasionally required.[8] It has been suggested that left ventricular stimulation be used routinely in patients in whom right ventricular stimulation fails to induce VT while the patient is receiving drugs.[9] Although certain general factors influencing the ability of programmed stimulation to initiate tachycardias are known, the determinants of the mode of initiation in individual patients are incompletely understood. The present study was undertaken to determine (1) the relation of the required mode of initiation and the distance between stimulation site and VT origin, (2) the effect of site of previous myocardial infarction on mode of initiation, and (3) the relation between the method of initiation and the cycle length of VT.

characteristics of the study population are summarized in Table I. Left ventricular endocardial catheter mapping was done in 38 patients to localize the site of origin of the VT.

Electrophysiologic study: Electrophysiologic study was performed in the postabsorptive state. Antiarrhythmic agents were discontinued for at least 5 half-lives before study in all patients. Two to 6 electrode catheters were inserted percutaneously through the femoral or brachial vein and positioned in the heart under fluoroscopic guidance. Routinely, catheters were positioned in the high right atrium, His bundle region, coronary sinus, and right ventricular apex. Our stimulation protocol has been reported previously in detail.[2,3,10]

Protocol: The protocol involved 4 stages. (1) Single and double ventricular premature extrastimuli were introduced during at least 2 paced cycle lengths (S_1-S_1 most often 600 and 400 ms) from 1 to 3 right ventricular sites. All patients were studied from the right ventricular apex. Single premature stimuli (S_2) were introduced late in diastole and moved to progressively shorter coupling intervals by 10 ms decrements until ventricular refractoriness was reached. Double premature stimuli were then introduced (S_2-S_3) with the S_1-S_2 interval 50 to 100 ms longer than the ventricular effective refractory period and the S_2-S_3 interval at twice the S_1-S_2 interval. The S_2-S_3 interval was then shortened by 10 ms decrements until S_3 reached refractoriness. The S_1-S_2 interval was then shortened by 10 ms decrements until S_3 evoked a response. This process was continued until S_2 and S_3 were refractory. Bursts of rapid ventricular pacing or triple premature ventricular depolarizations were then performed. Triple extrastimuli were given in all patients in whom double extrastimuli or rapid ventricular pacing failed to initiate VT. (2) Rapid ventricular pacing (15 to 30 seconds) to a cycle length of 250 ms was delivered from 1 right ventricular site. (3) Triple premature stimuli (S_3-S_4) were introduced in a fashion similar to that used previously for double premature stimuli with the S_1-S_2 interval 50 to 100 ms longer than the ventricular refractory period and the S_2-S_3 interval and S_3-S_4 interval 2 and 3 times the S_1-S_2 interval, respectively. (4) If VT was not initiated by the foregoing techniques, stimulation from the right ventricular mid-septum, outflow tract, and left ventricle was employed using a similar protocol.

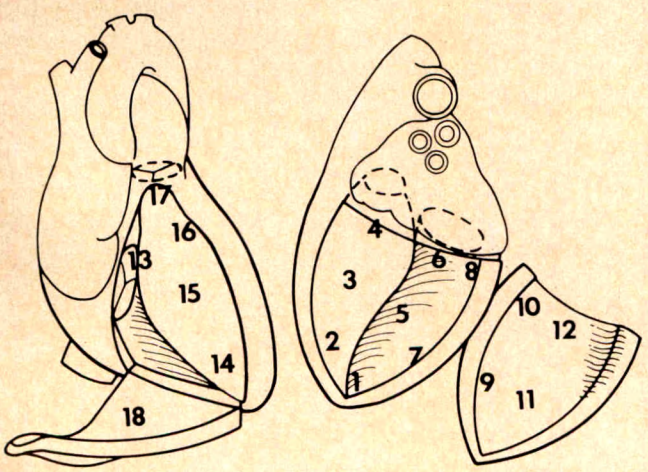

FIGURE 1. Schema of left ventricular endocardial catheter mapping sites used in our patients in the left anterior oblique projection. Site 1 represents the left ventricular apex, sites 2 to 4 are septal, sites 5 and 6 are inferior, sites 6, 8, and 10 are basal along the mitral valve ring, and sites 7, 9, 11, and 12 are on the left ventricular free wall. Sites 13 to 17 are right ventricular septal sites at the tricuspid valve, apex, mid and high septum, and outflow tract, respectively. Site 18 is the right ventricular free wall.

Stimulation was performed with a specially designed programmable stimulator (Bloom Associates, Narbeth, Pennsylvania). The stimuli were rectangular pulses 1 ms in duration delivered at twice diastolic threshold. Intracardiac electrograms were filtered at 30 to 500 Hz and simultaneously displayed with 2 to 3 surface electrocardiographic leads, usually leads I, aVF, and V_1 on a multichannel oscilloscope (Electronics for Medicine VR12 or VR16), stored on analog tape (Honeywell 5600), or later retrieved on photographic paper and simultaneously recorded with a jet-ink recorder (Elema Mingograf) at paper speeds at 100 to 200 mm/s for real-time analysis.

Endocardial catheter mapping: The catheters used for mapping included quadripolar woven dacron catheters with a 0.5 cm intraelectrode distance (USCI, Billerica, Massachusetts), and modified USCI cournand catheters with electrodes 1.5 mm apart (Wilton Webster, Los Angeles). Six right ventricular sites and 12 to 15 left ventricular sites were mapped during sinus rhythm and during VT. Each preselected site (Fig. 1) was verified by multiple plane fluoroscopy. The site of origin of the VT was defined as the site demonstrating the earliest recorded discrete or fragmented ventricular electrogram during VT using the electrode pair with a 1 cm interelectrode distance. The technique of endocardial catheter mapping has been reviewed in detail elsewhere.[4,5] In those tachycardias in which the origin was localized by catheter mapping, the distance between the site of stimulation and the site of origin of the VT was determined. If the site of origin was at the site of stimulation or at an adjacent site (on the same or opposite side of the ventricular septum), it was considered close (for example, stimulation site at site 14 and site of origin at site 2). This generally corresponded to an estimated distance of <3 cm. When the site of stimulation was ≥ 3 sites removed from the site of origin, this was considered distant and corresponded to an estimated separation of > 3 cm (for example, site of stimulation at site 14 with a site of origin at 10). When the site of stimulation was 2 sites away from the origin, it was termed intermediate and corresponded to a distance of 3 to 5 cm (for example, stimulation site 14 with a site of origin at 5). For this aspect of the study, stimulation was always performed from the right ventricular apex. Analysis of variance, chi-square, and unpaired student's *t* test were used for statistical analysis.

Results

Mode of initiation versus distance between site of origin and stimulation: In 38 patients the site of origin of VT was determined by endocardial catheter mapping. These patients were separated into 3 groups to compare the mode of initiation and the distance be

tween the site of stimulation and the site of origin of VT when the site of stimulation was close, intermediate, or distant from the stimulation site. In all cases stimulation was performed from the right ventricular apex. Of 11 patients whose VT site of origin was close to the stimulation site, 1 required a single extrastimulus, 6 required double extrastimuli, 2 required triple extrastimuli, and 2 required rapid pacing for initiation of their VT (Fig. 2). In patients in whom the distance was intermediate, 1 required a single extrastimulus, 5 required double extrastimuli, 1 required triple extrastimuli, and 1 required rapid pacing. Finally, in those patients in whom the site of origin was distant from the stimulation site, 3 required a single extrastimulus, 11 required double extrastimuli, 5 required triple extrastimuli, and none were initiated with rapid pacing. There was no difference in the stimulation protocol required to initiate VT when the site of origin was close, intermediate, or distant from the stimulation site (Fig. 2). Most patients required double extrastimuli for initiation in each of the groups.

Mode of initiation versus site of previous myocardial infarction: In 69 patients who had VT initiated from the right ventricular apex, the mode of initiation was compared with the site of previous myocardial infarction by surface electrocardiography (Fig. 3). In patients with anteroseptal myocardial infarction, 6 were induced with a single extrastimulus, 5 were induced with double extrastimuli, 7 were induced with triple extrastimuli, and 2 were induced with rapid ventricular pacing. In patients who had an inferior wall myocardial infarction, 6 were induced by a single extrastimulus, 10 were induced by double extrastimuli, 10 were initiated by triple extrastimuli, and none were initiated with rapid pacing. In patients with lateral wall myocardial infarction, 2 were induced with a single extrastimulus, 7 were induced with double extrastimuli, 2 were induced with triple extrastimuli, and none were induced with rapid ventricular pacing. In patients with multiple myocardial infarctions, 4 were induced with a single extrastimulus, 7 were induced with double extrastimuli, 1 was induced with triple extrastimuli, and none were induced with rapid ventricular pacing. No correlation was found between the site of previous myocardial infarction and the method of initiation.

Distance between site of origin and stimulation site versus cycle length of tachycardia: The cycle length of VT when the site of origin was close (mean 304 ± 69 ms), intermediate (mean 356 ± 63 ms), or distant (mean 325 ± 57 ms) from the stimulation site were not significantly different.

Mode of induction versus cycle length of VT: In the 104 patients, 126 morphologically distinct tachycardias were induced (for instance, contralateral bundle branch block pattern or difference in mean QRS axis ≥90°, Table II). The mean cycle length of VT in patients induced with a single extrastimulus was 342 ± 72 ms; in those induced with double extrastimuli, 295 ± 60 ms; in those induced with triple extrastimuli 282 ± 56 ms, and in those induced with rapid pacing, 293 ± 40 ms. The mean cycle length of VT induced with a single extrastimulus was significantly longer than that of VT induced with double or triple extrastimuli or rapid pacing. There were no significant differences among the latter 3 groups. The numbers of patients who required right ventricular outflow tract or left ventricular stimulation for initiation of VT are too small to analyze separately.

Discussion

Programmed electrical stimulation is a technique that has been demonstrated to be both sensitive and specific in replicating the laboratory clinical VT, and in predicting the success or failure of a drug regimen.[6,7,11] Until recently, most laboratories have used single and double extrastimuli and rapid ventricular pacing as their stimulation protocol.[2,12,13] Currently, triple extrastimuli also are used. It has been stated that more vigorous stimulation may be needed if there is more intervening tissue between the stimulation site and the site of origin of the VT.[14] It has even been suggested that left ventricular stimulation be used routinely in as-

sessing drug therapy in patients who are noninducible with right ventricular stimulation.[9] An unexpected finding in the study was the lack of correlation between the vigor of the stimulation protocol required to initiate VT and the distance between the site of stimulation and the site of origin. Early in the clinical experience with programmed stimulation, it was noted that VTs terminated with single extrastimuli had longer cycle lengths or were closer to the site of stimulation (usually >350 ms, isilateral ventricle), or both, than those terminated with double extrastimuli (usually <350 ms, contralateral ventricle).[2] It was thus reasoned that the amount of interevening tissue and, hence, the site of stimulation could influence the mode of initiation.

It was also observed in patients with the preexcitation syndrome that circus movement supraventricular tachycardias utilizing a left-sided Kent bundle could occasionally not be initiated from a right-sided chamber, whereas they could be easily started by left atrial stimulation.[15] Site of stimulation in this case appeared to relate both to the ease of creating unidirectional block and the ability of that area to recover excitability so that it could be reexcited. This observation was subsequently applied to stimulation techniques employed to initiate VT.[2,12] Previous studies from our laboratory[8] suggested that no clinical electrocardiographic, hemodynamic, angiographic, or electrophysiologic characteristics were able to identify the 12 of 108 patients with VT who required left ventricular stimulation for induction of their arrhythmias. Specifically, the location of previous myocardial infarction and right or left ventricular refractoriness did not separate this group from the other patients. No explanation was readily apparent to explain the failure of right ventricular stimulation in these patients.

We also have correlated the distance between the site of origin and stimulation site with the cycle lengths of the VT induced. If, by chance, VT distant from the site of stimulation was slower as a group, they would be more likely to be initiated by less vigorous stimulation techniques (that is, single premature extrastimuli). This could obscure the expected findings of a more vigorous protocol required to initiate VT at a distant site. There were, however, no differences among cycle lengths of VT induced when the site of origin was close, intermediate, or distant from the stimulation site. Although in all c our patients the data were related to induction from th right ventricular apex, in the small number of patient who required a different site of stimulation for induc tion, the distance of the stimulation site from the sit of origin of the VT did not appear to influence th number of extrastimuli required to initiate the VT c its cycle length. There are too few of such patient however, for statistical analysis.

There are obvious difficulties in estimating distanc from stimulation site to origin site. The largest potenti source of error is the difference in heart size amon patients. To overcome this difficulty, we also compare the location of previous myocardial infarction by elec trocardiogram with the mode of initiation in those pa tients in whom VT was induced from the right ver tricular apex. This site was chosen since it is reasonabl reproducible from patient to patient. These result confirmed the lack of correlation between the mode c initiation and distance from stimulation to origin see with left ventricular mapping. Patients with multipl infarctions, in whom conduction of the stimulated im pulse presumably would travel through more abnorma tissue, did not require more vigorous stimulation tech niques for the initiation of VT. Thus, no explanation immediately apparent to rationalize the discordanc between distance from site of stimulation to site of V origin and mode of initiation. It may be necessary t examine 3-dimensional propagation of wavefronts an development of local block to fully develop the questio Perhaps a narrow isthmus to the site of initial block required to initiate reentry.

Our results demonstrate that VT induced with single extrastimulus was slower than those induced wit double or triple extrastimuli or by rapid pacing. Ther was no difference among the latter 3 groups. Th suggests that in the VT initiated with a single extra stimulus, conduction may already be markedly slowe with respect to refractoriness and that additional ex trastimuli are not required to prolong conduction. Th slowed conduction could, of course, explain the longe cycle lengths of these tachycardias. The fact that drug which further prolong conduction and slow VT cyc length frequently facilitate VT induction, that is, de crease the number of extrastimuli required for initia tion, supports this hypothesis.[16] Why VT initiated wit triple extrastimuli were not more rapid than those in duced with double extrastimuli is not apparent, bu there are several plausible explanations. The effects o refractory periods may be maximized after 2 prematu ventricular depolarizations. The added extrastimu may, thus, either fail to shorten refractoriness or b contrabalanced by further prolongation in conductio in the other limb of the VT. The third possibility is tha cycle length is not related to refractoriness.

Cardiac Arrest in Young, Ostensibly Healthy Patients: Clinical, Hemodynamic, and Electrophysiologic Findings

D. WOODROW BENSON, Jr., MD, PhD, DAVID G. BENDITT, MD, ROBERT W. ANDERSON, MD, ANN DUNNIGAN, MD, MARC R. PRITZKER, MD, THOMAS J. KULIK, MD, and JAMES H. ZAVORAL, MD

This study examines the clinical, hemodynamic, and electrophysiologic findings in a unique group of 11 young (aged 15 months to 29 years) survivors of a cardiac arrest. All patients were previously in good health, and cardiac arrest was the initial manifestation of cardiac disease in all. Overt clinical and hemodynamic abnormalities were not as common as previously reported, and in some instances apparent cardiac abnormalities failed to provide a link to cardiac arrest. No patient had congenital heart disease or hypertrophic cardiomyopathy. However, during multicatheter electrophysiologic study, sustained tachyarrhythmia was reproducibly initiated in 8 of 11 patients (73%).

Young, ostensibly healthy patients who survive cardiac arrest form a diverse group. Diligent programmed intracardiac electrical stimulation may demonstrate life-threatening tachycardias in these patients. Treatment to prevent recurrence of cardiac arrest is difficult in this group of patients. However, the ability to initiate tachycardia in the electrophysiologic laboratory may be useful in the management of these patients.

Cardiac arrest in young, ostensibly healthy patients is uncommon, and to date most studies of this problem have described findings at postmortem cardiac examination of the unresuscitated victims. Previous studies have concluded that in the young cardiac arrest victim, associated cardiac disease, either congenital or acquired, is nearly always present, and an antemortem diagnosis of cardiac disease has usually been made.[1–5] In an international cooperative study of 254 cases of sudden unexpected death in victims aged 1 to 21 years, only 8 (3%) had no previous history of cardiovascular disease.[1] Postmortem examinations have identified congenital heart disease,[1] myocarditis,[1,2] dilated cardiomyopathy,[1,4] hypertrophic cardiomyopathy,[3] and intramyocardial coronary artery[5] as causes of cardiac arrest in young patients. Studies of young survivors of cardiac arrest have been limited to case reports,[6,7] and it has been difficult to develop a profile of victims of this problem. This report presents results of evaluation of 11 young survivors of cardiac arrest whose initial manifestation of cardiovascular disease was cardiac arrest.

Methods

Patient description: During the period from January 197 to July 1982, we evaluated 11 patients (8 male, 3 female) age 15 months to 29 years (mean 18 years) who had been successfully resuscitated from out-of-hospital cardiac arres Cardiac arrest was determined to have occurred if the patien became unresponsive and required cardiopulmonary resuscitation, direct-current cardioversion, or both. In all case ventricular fibrillation (VF) (10 patients) or sustained ven tricular tachycardia (VT) (1 patient) was diagnosed b paramedical or emergency room personnel.

Clinical studies: The initial evaluation of each patien included complete history and physical examination wit special emphasis on cardiovascular and neurologic examina tion. Electrocardiography, ambulatory (minimum 48 hours or continuous surveillance bedside monitoring, and echocar diography were performed in all patients. Nine patients un derwent cardiac catheterization with coronary angiograph and ventriculography, and 7 patients had graded exercis

testing. Transient anoxic encephalopathy was common, and most patients underwent electroencephalography, cerebral computerized axial tomography, or both as part of the neurologic evaluation. All patients were considered neurologically normal within 2 weeks after cardiac arrest.

Electrophysiologic evaluation: Each patient underwent multicatheter electrophysiologic studies within 1 to 4 weeks of cardiac arrest except Patient 10, who underwent study 1 year after cardiac arrest. All cardioactive drugs were discontinued for at least 3 drug half-lives. Three or four 5Fr or 6Fr multielectrode catheters were inserted percutaneously through the femoral, antecubital, and/or subclavian veins and positioned at specific intracardiac sites (right ventricular apex, His bundle recording site, right atrium, coronary sinus) as needed. Before January 1980, we performed cardiac electrical stimulation using a stimulator limited to only 2 extrastimuli; subsequently, a stimulator capable of delivering up to 4 premature stimuli was utilized. Impulse duration was 1 to 2 ms with current strength twice diastolic pacing threshold.

Due to the development of testing techniques over time, the pacing protocol varied. However, in each patient the initial electrophysiologic assessment examined characteristics of atrioventricular and ventriculoatrial conduction. Patients found to have accessory atrioventricular connections then underwent extensive studies to evaluate both their location and electrophysiologic properties with special emphasis on analysis of ventricular cycle lengths during atrial fibrillation.[8]

Ventricular stimulation was performed in all patients. Ventricular pacing trains and extra stimuli were inserted at the right ventricular apex in all patients. For purposes of this study, sustained VT was diagnosed if a single episode resulted in ≥30 QRS complexes. The pacing protocol consisted of sequential insertion of from 1 to 4 extrastimuli after an 8 to 10 beat pacing train at cycle lengths 500 ms and then 400 ms. Each extrastimulus was progressively scanned through diastole until it no longer captured, at which point it was fixed at 20 to 30 ms beyond the point of retractoriness; the next extra stimulus was then added and scanning of diastole was repeated. This process was repeated until all 4 extrastimuli (or 2 extrastimuli for early studies) were applied. The process was terminated if sustained VT was provoked. If no arrhythmias were induced by this method, right ventricular burst pacing, consisting of asynchronous insertion of 2 back-to-back trains of 6 to 8 ventricular stimuli at progressively decreasing cycle lengths (300 to 240 ms), was performed. In Patient 9, this protocol was repeated in both the right and left ventricles before and during isoproterenol infusion (0.05 μg/kg/min).

TABLE I Clinical Features

Patient	Age (yr) & Sex	Prior Symptoms or Diagnosis	Activity at Cardiac Arrest

8	18M	. . .	Running
9	18M	Palpitations	Wrestling
10	12M	. . .	Running
11	21M	. . .	Standing

Treatment: In 3 of the first 4 patients, sustained tachyarrhythmias could not be induced; their treatment was empirical. This usually consisted of propranolol alone or in combination with phenytoin. In subsequent patients, all of whom had inducible tachycardia, serial electrophysiologic studies were performed in the presence of an antiarrhythmic treatment regimen with a view toward establishing a treatment program which prevented induction of sustained tachycardia. In some patients, it was not possible to achieve this goal with available antiarrhythmic drugs or surgery. Consequently, investigational antiarrhythmic drugs (bethanidine sulfate, amiodarone) were evaluated. We used amiodarone as the treatment of last resort, and for this drug, electrophysiologic testing of efficacy was not performed.[9]

After hospital discharge, patients were returned to the care of their referring physician. The patients were referred from a wide geographic region and personal follow-up was not possible in all cases. Therefore, for some patients, follow-up information was updated quarterly based upon telephone contact with either the patient or the patient's physician.

Results

Table I summarizes the clinical features of the 11 patients. Table II summarizes the findings of their cardiovascular evaluation, and Table III summarizes the findings of their electrophysiologic evaluation and treatment.

Five patients were engaged in or recovering from mild to moderate exercise at the time of cardiac arrest. The remaining 6 were relatively sedentary; 2 patients were sleeping at the time of cardiac arrest (Table I). Before

AF = atrial fibrillation; CL = cycle length; DPH = diphenylhydantoin; LLAC = left lateral accessory connection; PSAC = posterior septal accessory connection; Pt = patient; SVT = supraventricular tachycardia; VF = ventricular fibrillation; VT = ventricular tachycardia; + = present; 0 = absent.

cardiac arrest, all patients were free of cardiovascular symptoms except for Patients 1, 3, and 9, who had had occasional palpitations which had been present for 1 month to 3 years and had not required medical attention. Patient 7 had a 4-year history of mild symptoms of Raynaud's phenomenon. No other patient had any recognized chronic medical problem, and none were taking any chronic medication at the time of cardiac arrest. There were no other cases of cardiac arrest in first order relatives.

Cardiovascular evaluation: In 8 patients, standard electrocardiograms were normal (Table II). One patient had classic electrocardiographic features of Wolff-Parkinson-White syndrome, 1 patient had a short P-R interval (0.11 second), and 1 patient had nonspecific ST-T–wave changes. The Q-T interval was normal in all patients. Ambulatory or bedside monitoring showed no abnormalities in 7 patients. VT was observed in Patients 4 and 6; Patient 6 required direct-current cardioversion of spontaneously occurring VT during hospital admission. In this patient, VT initiated during electrophysiologic study was identical to the spontaneous episode. Multimorphic ventricular premature contractions were seen in Patients 3 and 11.

Single and 2-dimensional echocardiograms were normal in 8 of 11 patients. A dilated left ventricle with poor wall motion was present in Patients 6 and 11. Prolapse of the tricuspid valve associated with auscultatory findings of mild tricuspid regurgitation was seen in Patient 9.

Treadmill exercise testing was normal in 4 of 7 patients (Bruce protocol). Baseline ventricular ectopy increased with exercise in Patient 3, and S-T segment depression developed in Patient 10. Supraventricular tachycardia (cycle length 220 ms) associated with S-T segment depression and hypotension developed in Patient 9 (Fig. 1).

Cardiac catheterization with angiography was performed in 9 patients. Intracardiac pressure measurements were normal in 8 of 9 patients, but Patient 10 had a markedly elevated left ventricular end-diastolic pressure. Coronary angiography was normal in 8 patients, but in Patient 10 external systolic compression of the left anterior descending coronary artery by myocardial bridges (approximately 75% reduction in coronary artery diameter) was present. Ventriculograms were normal in 6 of 9 patients. A right ventriculogram confirmed the echocardiographic impression of mild tricuspid valve prolapse and regurgitation in Patient 9. Patients 6 and 11 had large dilated left ventricles with ejection fractions of 34 and 39%. Patient 7 had mild left ventricular dysfunction with an ejection fraction of 51%.

Cardiovascular diagnosis: After cardiac arrest, a cardiovascular diagnosis was made in 6 patients (Table II). Based on an increase in titers to Coxsackie B-2 virus

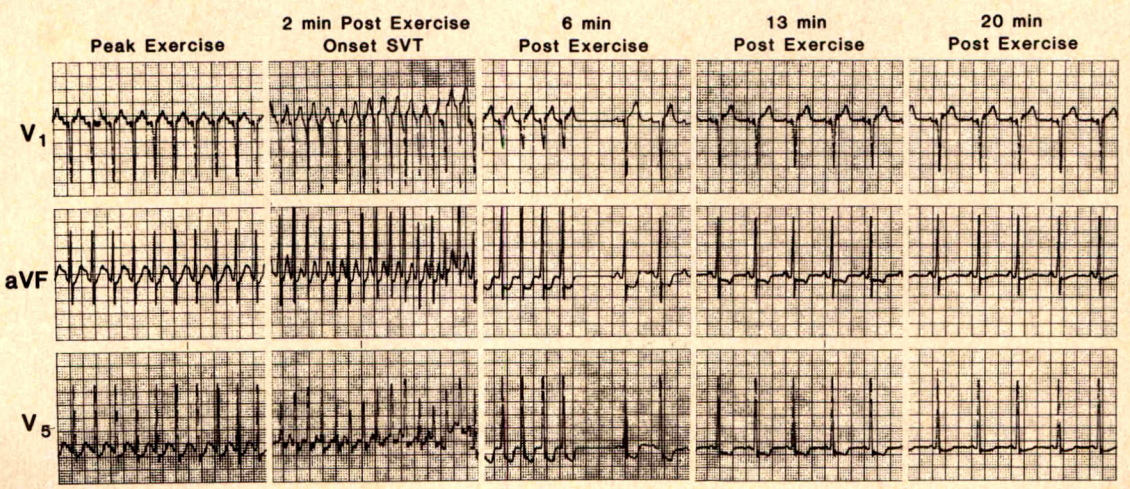

FIGURE 1. Spontaneous onset of orthodromic reciprocating tachycardia during treadmill exercise in Patient 9. In this instance, tachycardia began 2 minutes after exercise. Initially, the cycle length of the tachycardia is short (220 ms), but it gradually lengthens and tachycardia spontaneously terminates in about 4 minutes. The patient felt compelled to sit during tachycardia. While sitting, his peak systolic blood pressure was 100 mm Hg. Transient S-T segment abnormalities developed during exercise but returned to normal within 11 minutes. SVT = supraventricular tachycardia.

Patient 4 was thought to have viral myocarditis. Patients 6, 7, and 11 had dilated cardiomyopathy; in Patient 7, a diagnosis of collagen vascular disease, probably scleroderma, was suspected. Patient 9 had tricuspid valve prolapse. Patient 10 had myocardial bridges and a restrictive cardiomyopathy. No patient was found to have congenital heart disease, hypertrophic cardiomyopathy, or arrhythmogenic right ventricular dysplasia.[10]

Electrophysiologic evaluation: Rapid sustained tachycardia was initiated in 8 patients (73%) and in 3 patients either no arrhythmia or VT of <4 beats was observed. The 3 patients without inducible arrhythmia were studied early in our experience when the stimulation protocol was limited to 2 extrastimuli. VF did not occur during catheter study in any patient, presumably due to prompt cardioversion of hemodynamically deleterious arrhythmias.

Accessory atrioventricular connections were demonstrated in 2 patients. Patient 8 had a posterior septal accessory connection with only anterograde conduction, which participated in antidromic tachycardia that degenerated to atrial fibrillation. Isoproterenol administration during atrial fibrillation resulted in R-R intervals as short as 180 ms.[7] Patient 9 had a left lateral accessory connection which conducted only in the retrograde direction; ventricular preexcitation was never seen. This accessory connection participated in orthodromic tachycardia (cycle length 220 to 290 ms) which was associated with hypotension at short cycle lengths (peak systolic blood pressure as low as 60 mm Hg in supine position). To exclude a propensity to VT, this patient also underwent stimulation of both ventricles with 4 sequential extrastimuli before and during isoproterenol infusion. VT was not induced.

In 6 patients, rapid, sustained VT was initiated. Profound hypotension associated with induced VT necessitated direct-current cardioversion in all 6 patients on 2 or more occasions. In each patient, characteristics of VT were similar to previously initiated episodes. In Patient 1 this was accomplished by rapid atrial pacing. In Patients 5, 6, 7, 10, and 11 this was accomplished by sequential insertion of 3 or 4 extrastimuli from the apex of the right ventricle (Fig. 2).

Treatment: Recurrences of cardiac arrest (3 of 11) or symptomatic VT (3 of 11) were common, even when antiarrhythmic drugs were employed. Table III summarizes the therapy for all patients. A number of factors played a role in selection of therapy in individual patients. Early in our experience, serial electrophysiologic drug testing was not part of our routine management of cardiac arrest survivors. In the first 4 patients, we relied on empiric treatment usually with propranolol, alone or combined with phenytoin. However, all 4 patients treated with these empiric regimens had recurrences and 2 died.

One month after cardiac arrest, Patient 10 underwent surgery for release of myocardial bridges. One year after surgery, coronary and left ventricular angiography were normal; however, hemodynamic evidence of restrictive cardiomyopathy remained. Electrophysiologic testing, which was previously deferred because of concerns that ventricular ischemia was present, was performed 1 year after surgery. This patient withdrew from testing before a satisfactory treatment regimen could be found, and he was discharged on no therapy. However, 23 months after his initial presentation, he had a second cardiac arrest.

Both Patients 8 and 9 underwent surgery for ablation of accessory connections, and they have done well in follow-up of 8 and 14 months. Serial electrophysiologic testing of antiarrhythmic drug effects were performed in Patients 5, 6, 7, 10, and 11. When VT could no longer be induced by electrical stimulation, therapy was considered adequate. In Patients 6 and 7, quinidine sulfate prevented the initiation of VT, but both patients had

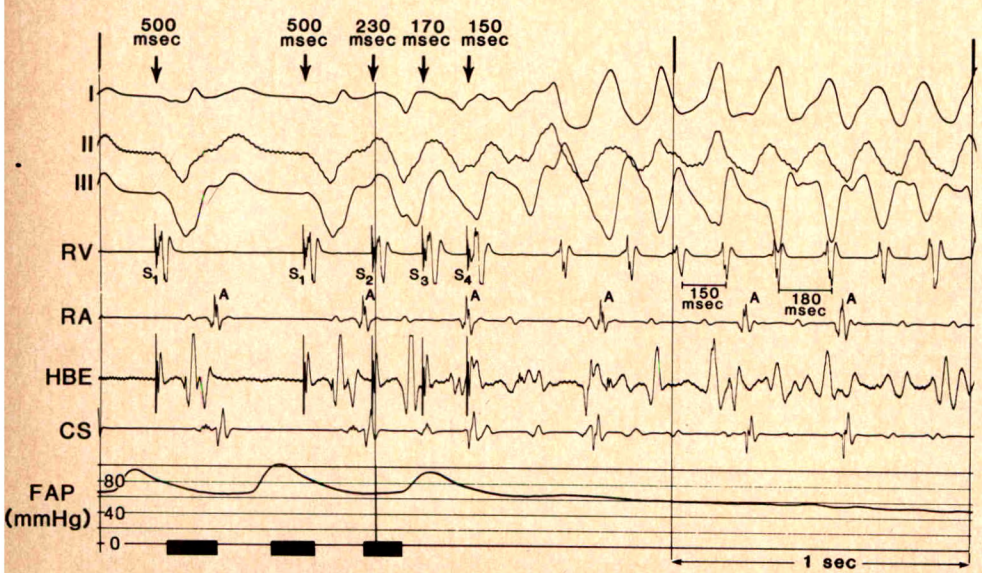

FIGURE 2. Initiation of rapid, sustained ventricular tachycardia in Patient 11 with 3 sequential extrastimuli (S_2, S_3, S_4) after a basic drive (S_1) at 500 ms. Direct-current cardioversion was required to terminate this episode of ventricular tachycardia. I, II, III = standard surface electrocardiograms; CS = electrograms from coronary sinus; FAP = femoral artery pressure; HBE = His bundle electrogram; RA = right atrial electrogram; RV = right ventricular electrogram.

a recurrence. Patient 6 died; Patient 7 was treated with amiodarone. In Patients 10 and 11, antiarrhythmic drugs with acceptable adverse effects that prevented the initiation of VT were not found; they were treated with amiodarone. Electrophysiologic testing of amiodarone was not performed in Patients 7, 10, and 11. All 3 patients have done well with amiodarone during short follow-up (1 to 8 months).

Postmortem examination: Patients 2 and 6 underwent postmortem cardiac examination by a medical examiner. No structural defects were found in Patient 2. Patient 6 had typical findings of dilated cardiomyopathy.

Discussion

Young, ostensibly healthy patients who survive cardiac arrest form a diverse group. The major finding of our study is that a rapid tachyarrhythmia could be induced in most (73%) of these patients. It is presumed that a spontaneously occurring tachyarrhythmia with deleterious hemodynamic consequences, similar to that initiated during electrophysiologic study, was the basis for cardiac arrest. This possibility was confirmed in 1 case.

The percentage of our patients with inducible arrhythmia compares well with results of previously reported studies of patients with[11] and without[12] coronary artery disease. The use of electrophysiologic testing as a guide to selection of therapy to prevent recurrences is not as encouraging as reported in older survivors of cardiac arrest.[11,12] One explanation for this apparent disparity could be the small number of patients we studied. Alternatively, cardiac arrest in some patients may represent an early manifestation of a progressive disease. Two patients illustrate this point well. Cardiac arrest was the initial manifestation of disease in Patient 6, but during evaluation, dilated cardiomyopathy was found. Progression of disease was suggested by symptoms of heart failure which appeared 1 year later. A fatal recurrence of cardiac arrest occurred 18 months after initiation of therapy which had prevented induction of VT. Patient 7 had a nonfatal recurrence of VT while taking therapy which had prevented induction of VT. Concomitantly, further progression of collagen-vascular disease, probably scleroderma, was noted with pulmonary and renal involvement. If other patients with recurrences live long enough, they may have additiona manifestation of disease. This seems especially true fo patients with cardiomyopathy.

Our study differs from those previously reporte since we studied survivors. As in previous studies, w found that associated cardiovascular abnormalities wer common, but in only 5 of 11 patients were they likely t have been etiologic in cardiac arrest (myocarditis 1 cardiomyopathy 4). However, findings in other patient suggest that there may not always be a link between a overt cardiac abnormality and cardiac arrest. For ex ample, Patient 9 was found to have tricuspid valv prolapse and a left lateral accessory connection. Su praventricular tachycardia was the only arrhythmi induced even though aggressive stimulation of bot ventricles, before and during isoproterenol infusion, wa performed. If this patient had not been resuscitate from cardiac arrest, tricuspid valve abnormalities ma have been noted at autopsy and might have been con sidered etiologic in the patient's cardiac arrest.

Value of the Ajmaline-Procainamide Test to Predict the Effect of Long-Term Oral Amiodarone on the Anterograde Effective Refractory Period of the Accessory Pathway in the Wolff-Parkinson-White Syndrome

PEDRO BRUGADA, MD, WILLEM R. DASSEN, PhD, SIMON BRAAT, MD, ANTON P. GORGELS, MD, and HEIN J. J. WELLENS, MD

In patients with the Wolff-Parkinson-White syndrome, intravenous ajmaline (50 mg administered over 3 minutes) or procainamide (10 mg/kg body weight administered over 10 minutes) is helpful in defining the duration of the anterograde effective refractory period of the accessory pathway. In this study the value of the ajmaline-procainamide test to predict the effects on the anterograde effective refractory period of the accessory pathway of long-term oral amiodarone were assessed. Thirty-six patients with the Wolff-Parkinson-White syndrome were studied. Twenty-four (Group A) had a negative result of the ajmaline-procainamide test and a mean duration of the anterograde effective refractory period of the accessory pathway of 237 ± 24 ms. Twelve (Group B) had a positive result in the ajmaline-procainamide test (disappearance of preexcitation during sinus rhythm after administration of ajmaline and procainamide) and a duration of the anterograde effective refractory period of the accessory pathway of 284 ± 25 ms ($p < 0.05$ versus values in Group A). Amiodarone prolonged the anterograde effective refractory period of the accessory pathway by 53 ± 35 ms in patients in Group A to 290 ± 37 ms ($p < 0.001$) and by 100 ± 85 ms in patients in Group B to 384 ± 94 ms ($p < 0.001$). The difference in mean increase between both groups was not significant. In most patients (83%) in Group A amiodarone prolonged the anterograde effective refractory period of the accessory pathway to 260 to 330 ms. However, in most patients (83%) in Group B, amiodarone prolonged the anterograde effective refractory period of the accessory pathway to ≥330 ms ($p < 0.01$). Thus, an ajmaline-procainamide test is of value in predicting the results of oral amiodarone on the anterograde effective refractory period of the accessory pathway.

In patients with the Wolff-Parkinson-White (WPW) syndrome, the intravenous administration of 50 mg of ajmaline over 3 minutes or 10 mg/kg body weight of procainamide over 10 minutes during sinus rhythm gives information about the duration of the anterograde effective refractory period of the accessory pathway. In most patients with the WPW syndrome with a duration of the anterograde effective refractory period of the accessory pathway ≥270 ms, both ajmaline[1] and procainamide[2] block anterograde conduction over the accessory pathway during sinus rhythm (a positive test). In most patients in whom the anterograde effective refractory period of the accessory pathway is <270 ms, ajmaline and procainamide fail to block anterograde conduction over the accessory pathway during sinus rhythm (a negative test).[1,2] Ajmaline is a class I antiarrhythmic agent not available in the United States. We have previously shown a good correlation between the effects of ajmaline and procainamide to block anterograde conduction over the accessory pathway in patients with the WPW syndrome.[2] Roughly 10 mg of ajmaline is equivalent to 100 mg of procainamide. Amiodarone is now being evaluated as an antiarrhythmic agent in the United States. Several studies have shown that it is of value in preventing both supraventricular and ven-

tricular arrhythmias.[3–9] In patients with WPW syndrome, amiodarone prolongs the anterograde effective refractory period of the accessory pathway more than other antiarrhythmic agents such as procainamide, ajmaline, and quinidine.[10] At present accurate assessment of the effect of an antiarrhythmic drug on the length of the anterograde effective refractory period of the accessory pathway in patients with the WPW syndrome requires an invasive electrophysiologic investigation.

In this study we evaluated the value of the ajmaline-procainamide test in predicting the effects of oral amiodarone on the duration of the anterograde effective refractory period of the accessory pathway. We wanted to know to what extent oral amiodarone was able to lengthen the anterograde effective refractory period of the accessory pathway in patients with both positive and negative results of the ajmaline-procainamide test. The results of such a study could be of value in providing noninvasive information about the effect of amiodarone on the anterograde effective refractory period of the accessory pathway in patients with the WPW syndrome.

Methods

Patients: Thirty-six patients (28 male and 8 female) with the WPW syndrome were retrospectively studied. Their ages ranged from 16 to 62 years. Four patients had a right-sided, 6 a septal, and 26 a left-sided accessory pathway. Patients were classified into 2 groups according to the results of the ajmaline and procainamide tests, which were performed as previously described.[1,2] Twenty-four patients had a negative ajmaline test result (Group A) and 12 patients a positive test result (Group B). Eleven patients in Group A and 7 in Group B also had a procainamide test performed, with results identical to those of the ajmaline test.

Twenty-four to 48 hours after the last test (ajmaline or procainamide), an electrophysiologic study was performed to determine the duration of the anterograde effective refractory period of the accessory pathway. The extrastimulus technique was used during atrial stimulation at at least 3 different basic cycle lengths of pacing, usually 600, 500, and 430 ms. The anterograde effective refractory period of the accessory pathway was defined as the longest A_1-A_2 interval not followed by anterograde conduction over the accessory pathway. The shortest measured anterograde effective refractory period of the accessory pathway at any cycle length of pacing from the atrial site closest to the atrial end of the accessory pathway was used. Patients were not included in this study when atrial refractoriness prevented accurate measurement of the duration of the anterograde effective refractory period of the accessory pathway during the control or repeat study on oral amiodarone. After the control study, patients were given amiodarone orally starting at a dose of 600 mg/day for 7 days followed by 200 mg/day for an additional 3 to 5 weeks. The total oral dose of amiodarone at the time of examination varied individually from 8,400 to 11,200 mg. During reexamination the same protocol was followed as during the initial electrophysiologic examination. The shortest value of the anterograde effective refractory period of the accessory pathway was used for analysis. Plasma levels of ajmaline, procainamide, and amiodarone were not determined. Statistical analysis was performed using the paired and unpaired Student's t test, and the chi-square test.

Results

A summary of the duration of the anterograde ef fective refractory period of the accessory pathway befor and after administration of amiodarone is shown i Table I. In patients in Group A (with negative result of the ajmaline-procainamide test), the mean duratio of the anterograde effective refractory period of th accessory pathway before administration of amiodaron was 237 ± 24 ms. This value was significantly differen from the duration of the anterograde effective refractor period of the accessory pathway in patients in Group I (290 ± 37 ms) ($p < 0.05$). One patient (Patient 20) i Group A had an anterograde effective refractory perio of the accessory pathway >270 ms (290 ms). One patien (Patient 35) in Group B had an anterograde effectiv refractory period of the accessory pathway <270 m (230 ms).

Amiodarone prolonged the duration of the antero grade effective refractory period of the accessor

pathway in both groups: in Group A by a mean of 53 ± 35 ms, and in Group B by a mean of 100 ± 85 ms. These results were statistically significant ($p < 0.01$ in both Group A and Group B versus values in control study). In one patient (Patient 21) in Group A and 1 (Patient 32) in Group B, amiodarone did not alter the duration of the anterograde effective refractory period of the accessory pathway. The mean increase in the anterograde effective refractory period of the accessory pathway in patients in Group B was greater than in those in Group A. However, the difference in mean increase was not significant ($p > 0.05$). When individual data were analyzed, it was observed that in 10 (83%) of 12 patients in Group B, amiodarone prolonged the anterograde effective refractory period of the accessory pathway to a value ≥330 ms; in 5 of these 10 patients it was ≥400 ms. In patients in Group A a duration of the anterograde effective refractory period of the accessory pathway ≥330 ms after administration of amiodarone was obtained only in Patients 7 and 20 (400 and 360 ms, respectively). In 20 of the remaining 22 patients the anterograde effective refractory period of the accessory pathway was 260 to 320 ms, and in the remaining 2 patients it was 220 and 230 ms. In this group, 20 (83%) of 24 patients had an anterograde effective refractory period of the accessory pathway of 260 to 330 ms during administration of amiodarone ($p < 0.01$ versus values in Group A).

Discussion

In this study patients with the WPW syndrome were classified into 2 groups on the basis of the results of the ajmaline-procainamide test. The duration of the anterograde effective refractory period of the accessory pathway as shown previously was significantly different in the 2 groups during the control study.[1,2] Amiodarone brought the anterograde effective refractory period of the accessory pathway to a duration of 260 to 330 ms in the majority of patients (83%) in Group A, and to a duration ≥330 ms in 83% of patients in Group B. We and others[11–13] found a relation between the duration of the anterograde refractory period of the accessory pathway in the WPW syndrome and the shortest preexcitated R-R interval during atrial fibrillation. One might assume therefore that in a majority of Group A patients (83%), the shortest R-R interval during atrial fibrillation will not be <260 ms during amiodarone administration (corresponding to a ventricular rate of 240 beats/min). In 83% of Group B patients the shortest R-R interval will not be <330 ms (corresponding to a ventricular rate of 170 beats/min) during administration of amiodarone. In our patients, however, atrial fibrillation was not systematically initiated during the study before and after administration of amiodarone, and these considerations should be made with caution.

The results of our study show that an ajmaline-procainamide test performed before antiarrhythmic therapy is helpful in predicting the results of oral administration of amiodarone and will help to avoid a repeat electrophysiologic investigation. We recently showed that beta-adrenergic stimulation shortens the duration of the effective refractory period of the accessory pathway in patients with the WPW syndrome.[14] The results of that study indicate that the properties of the accessory pathway are dynamic, and they change with changes in autonomic tone. At present the behavior of the properties of the accessory pathway with time are unknown, and it is possible that they are not stable. The results of this study, therefore, have to be considered with caution in light of these observations.

Evaluation of Metoprolol in Suppressing Complex Ventricular Arrhythmias

CRAIG M. PRATT, MD, SHEILA C. YEPSEN, RN, CVNS, M. G. KIM BLOOM, MD, ADDISON A. TAYLOR, MD, JAMES B. YOUNG, MD, and MIGUEL A. QUINONES, MD

This study documents the extent of suppression of premature ventricular beats which can be achieved with metoprolol, a semiselective beta-adrenergic blocking agent, at doses of 100 to 200 mg daily, utilizing a single-blind placebo-controlled 10-day protocol with continuous ambulatory electrocardiographic recording of 20 patients with cardiac disease and complex ventricular arrhythmias. Metoprolol (200 mg/day) resulted in suppression of 60% of total premature ventricular beats, with couplets (pairs) and ventricular tachycardia decreased 84% and 94%, respectively (all $p < 0.01$). Exercise-induced premature ventricular beats, especially ventricular tachycardia, were effectively suppressed. The peak plasma metoprolol level to achieve these results was 72 ± 34 ng/ml (mean ± 1 standard deviation). At this plasma concentration, the mean 24-hour heart rate during normal activity was reduced from 78 ± 8 beats/min (placebo) to 62 ± 4 (metoprolol 200 mg/day)($p < 0.001$). Beta blockade also was demonstrated by a 20% reduction in heart rate during maximal Bruce exercise testing with metoprolol 200 mg/day. Although resting left ventricular function was not affected by metoprolol, pulmonary function tests show a statistically significant decrease in forced vital capacity, forced expiratory volume in 1 second, and forced expiratory flow rates (25-75) reversible with a beta-2 agonist.

Ventricular rhythm disturbances have prognostic significance in identifying an increased risk for sudden cardiac death in patients after myocardial infarction.[1,2] Beta-adrenergic blocking agents are efficacious in suppressing ventricular arrhythmias, especially in specific clinical settings including catecholamine excess, digitalis toxicity, mitral valve prolapse, and those induced by exercise.[3–6] Importantly, in numerous prospective placebo-controlled randomized clinical trials of beta-blockers in patients after myocardial infarction, cardiac mortality and sudden cardiac death have been reduced. Propranolol, timolol, and metoprolol have achieved the most significant reduction in mortality and sudden death in these large clinical trials.[7–9] Although a reduction in mortality and sudden death has been documented, it has not been demonstrated that this reduction is due to suppression of ventricular arrhythmias.

Despite a substantial experience with beta-blockers the ventricular antiarrhythmic efficacy of metoprolol is poorly documented. Since the semiselective properties of this beta-blocker may be beneficial to patients with asthma or obstructive lung disease, this study was designed to assess the effect of metoprolol in suppressing complex ventricular arrhythmias, with concomitant measurement of left ventricular function, pulmonary function, and correlation with plasma metoprolol levels.

Methods

The study population consisted of 20 patients (10 male, 10 female; mean age 57 ± 8 years) with screening 24-hour ambulatory electrocardiograms demonstrating complex ventricular rhythm disturbances (frequent premature ventricular beats [PVB] ≥30 per hour, couplets, ventricular tachycardia [VT]). All 20 patients had documented cardiac disease: 15

patients had coronary artery disease documented by previous myocardial infarction, coronary arteriography or both; 2 patients had hypertensive heart disease; 3 patients had cardiomyopathy. All antiarrhythmic medications except digitalis were discontinued at least 72 hours before the study.

The study design consisted of a 10-day placebo-controlled single-blind protocol (3 days of placebo, 3 days of metoprolol 25 mg orally 4 times a day, 4 days of metoprolol 50 mg orally 4 times a day) with continuous 24-hour ambulatory electrocardiographic recordings. These were recorded on the Avionics® 445 A 2-channel system (Irvine, California) and analysis was performed on an Avionics 668 scanner. Tapes were analyzed by 2 independent investigators. Test tapes in our laboratory show a reproducibility of 92, 93, and 95% for total counts of PVB, couplets, and VT, respectively.

Ventricular arrhythmias, as well as heart rates during normal activity, were quantitated hourly during the entire 10-day study. Symptom-limited exercise testing was performed with placebo and metoprolol (200 mg/day) utilizing the standard Bruce protocol with quantitation of ventricular arrhythmias during exercise and recovery periods. Two-dimensional echocardiographic assessment of left ventricular function was performed during placebo and metoprolol dosing on an ATL® (Bellville, Washington) mechanical sector scanner and the left ventricular ejection fraction was calculated by a method previously reported from this laboratory.[10] Sector scans performed during placebo dosing on at least 2 consecutive days demonstrated a reproducibility of the left ventricular ejection fraction of ±3%.

Pulmonary function testing was performed during placebo, then 3 times during metoprolol dosing (2 hours after the first 25 mg dose, day 3 of 25 mg 4 times daily, 2 hours after first 50 mg dose).

Spirometry was performed on an Ohio® 850 rolling-seal spirometer (Madisonville, Wisconsin) utilizing a Collins Eagle® microprocessor (Braintree, Massachusetts). Forced vital capacity (FVC) and forced expiratory volume at 1 second (FEV_1) were selected from the best of ≥3 forced expiratory maneuvers. The mid-maximal expiratory flow rate (FEF [25-75]) was selected from the "curve" with the best total of FVC and FEV_1. Functional residual capacity and airway resistance were determined with an Ohio variable-pressure body plethysmograph. Total lung capacity was calculated from the functional residual capacity and the inspiratory capacity during a slow vital capacity maneuver. Spirometry and plethysmography were repeated 15 minutes after metaproterenol (1.5 mg) aerosolized inhalation. Data before and after bronchodilators were expressed from norms described by Morris,[11] Goldman,[12] Boren,[13] and their co-workers. Arterial blood gases were also obtained during placebo and metoprolol dosing.

• Metoprolol plasma samples were obtained during placebo administration, and once during low- and high-dose metoprolol with samples obtained 2 hours after each dose. Additionally, a 5-hour postdose sample was taken during high-dose metoprolol therapy. All plasma samples were obtained after at least 5 doses of metoprolol at each dose range to insure a steady state at the sampling time. Quantitation of metoprolol in human plasma was performed by fluorometry after high-pressure liquid chromatographic separation. Pronethalol was used as an internal standard. Known amounts of metoprolol ranging from 5 to 1,000 ng/ml were added to plasma samples obtained from persons taking no drugs; these samples were analyzed concurrently with those from patients taking metoprolol. A standard curve for metoprolol was then constructed by linear regression plot of metoprolol/pronethalol peak height ratio versus drug concentration in the spiked samples. Metoprolol concentration in the sample patient plasma was then calculated from the regression line by the formula $Y = mx + b$, where Y is the peak height ratio, m is the slope of the regression line, x is the metoprolol concentration, and b is the Y-intercept. This method allows detection of as little as 10 ng/ml of metoprolol with intraassay and interassay coefficients of variation of 5.4% and 8.3%, respectively. Commonly used cardiovascular drugs do not interfere with this assay.

Statistical analysis was performed with the *t* statistic for paired data. The Wilcoxon signed ranks test was used for data that were not normally distributed.

Results

Efficacy of metoprolol in suppressing ventricular arrhythmias: During 3 days of placebo ambulatory electrocardiographic recording, the mean premature ventricular beat frequency was 8,640/24 hours (Table I). Three days of low-dose metoprolol (25 mg orally 4 times daily) resulted in a mean reduction of PVB to 5,735/24 hours ($p < 0.01$ versus placebo). After 4 days of ambulatory electrocardiographic recording with high-dose metoprolol (50 mg orally 4 times daily), the mean frequency of PVB was further reduced to 3,536/24 hours ($p < 0.001$ versus placebo, $p < 0.02$ versus low-dose metoprolol). Of the 20 patients, 13 had ≥50% reduction in total PVB, 8 had >70% reduction, and 4 patients had >90% reduction in PVB.

Quantitation of ventricular couplets (Table II) revealed a progressive decrease in mean couplet frequency with low- and high-dose metoprolol—a maximal 84% reduction—which was highly significant ($p < 0.002$). Analysis of the 10 patients with VT during placebo

ambulatory electrocardiographic recording (Table III) showed a 94% reduction during high-dose metoprolol therapy, with total abolition of VT in 6 of 10 patients ($p < 0.01$).

Ventricular arrhythmias during maximal Bruce exercise testing were analyzed in 13 patients with both placebo and metoprolol dosing. During the placebo test, 10 of 13 patients had PVB during exercise or in the recovery phase, 7 of 13 had couplets, and 3 of 13 had exercise-induced VT. With metoprolol, in addition to an overall 70% decrease in total PVB, there was total abolition of couplets in 5 of 7 patients and elimination of exercise-induced VT in all patients.

In addition to the demonstrated reduction in mean heart rate with metoprolol, the degree of beta blockade was further verified by a decrease in double product during maximal Bruce exercise testing from placebo (23,237 ± 5,368) to high-dose metoprolol (15,500 ± 3,548) despite comparable exercise duration (6.32 ± 1.81 minutes versus 6.88 ± 2.07 minutes, placebo versus metoprolol therapy, respectively; difference not significant).

Metoprolol plasma levels: During low doses of metoprolol (100 mg/day) peak mean plasma metoprolol levels 2 hours after a dose were 33 ± 22 ng/ml. Peak mean plasma metoprolol levels at 200 mg/day dosage were 72 ± 34 ng/ml. Trough mean plasma metoprolol levels (5 hours after dosing) during high-dose metoprolol were 41 ± 45 ng/ml.

Mean heart rate for each 24 hours was quantitated over the 10-day period with continuous ambulatory electrocardiographic recording. There was a highly significant ($p < 0.001$) incremental decrease in the mean heart rate from placebo (78 ± 8 beats/min) to low-dose metoprolol (72 ± 6 beats/min, mean peak plasma metoprolol level 33 ± 22 ng/ml) and high-dose metoprolol (62 ± 4 beats/min, mean plasma metoprolol level 72 ± 34 ng/ml).

The peak plasma metoprolol level achieved during steady-state dosing in each patient during high-dose therapy is seen in Figure 1. There was no relation to this plasma level and the percent reduction of PVB on that day of ambulatory electrocardiographic recording ($p < 0.12$).

The relation between the mean heart rate during the hour each plasma metoprolol level was obtained (both peak and trough levels) is seen in Figure 2. There was a statistically significant correlation between plasma metoprolol concentration and the mean heart rate for the specific hours sampled ($r = 0.41$, $p < 0.001$).

Relationship of metoprolol therapy to ventricular function: Two-dimensional echocardiograms performed during placebo dosing demonstrated a mean resting left ventricular ejection fraction of 50 ± 10%

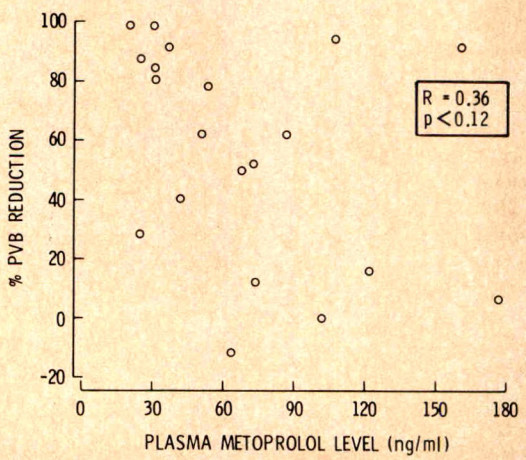

FIGURE 1. Relation of premature ventricular beat (PVB) reduction to maximal plasma metoprolol level achieved.

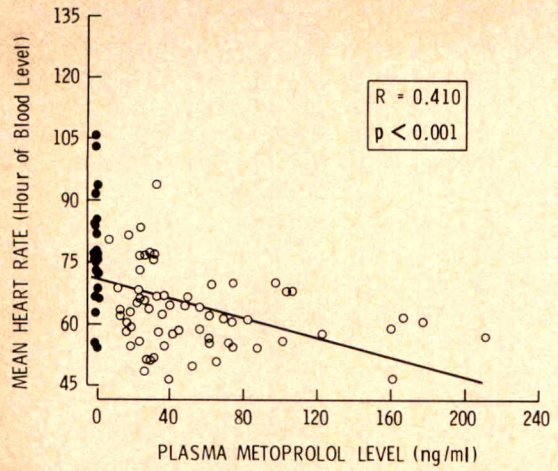

FIGURE 2. Mean heart rate during normal activity relative to metoprolol plasma concentration. **Closed circles,** placebo; **open circles,** metoprolol.

(range 22 to 71). There was no statistical difference in the ejection fraction with 200 mg/day of metoprolol (mean 48 ± 9.2%, range 31 to 68). No patient required discontinuation from the study because of clinical congestive heart failure; however, 1 patient did require increasing diuretic therapy while taking metoprolol (placebo ejection fraction of 32%, unchanged with metoprolol). Of the 4 patients with resting left ventricular ejections <40% with placebo, none had a further decrease in ejection fraction while taking metoprolol.

Relationship of metoprolol therapy to pulmonary function: Baseline pulmonary functions obtained in 18 patients during the placebo period revealed normal ventilatory function in 6, a mild restrictive defect in 4 (total lung capacity 80 to 90% predicted with normal FEV_1/FVC ratios), and obstructive airways disease in 8 (5 with FEF [25-75] <60% and normal FEV_1/FVC ratios, and 3 with FEF [25-75] <60% and reduced FEV_1/FVC ratios).

The mean FEV_1 during placebo therapy expressed as a percentage of predicted value was 89 ± 21%. After the first dose of 25 mg of metoprolol, the mean FEV_1 decreased to 85 ± 20% of predicted ($p < 0.013$). After 3 days of low-dose therapy, there was a further decrease in mean FEV_1 to 80 ± 23% of predicted ($p < 0.005$). After the first dose of 50 mg of metoprolol, this decrease was sustained; the mean FEV_1 was 81.5 ± 21% ($p < 0.001$) (Fig. 3).

The FVC and FEF (25 to 75) followed similar patterns. During placebo therapy, the mean FVC was 86 ± 11% of predicted, which decreased to 82 ± 14% with low-dose metoprolol, and to 80 ± 15% of predicted during the high-dose regimen ($p < 0.05$). The FEF (25 to 75) was 67 ± 38.5% before and 55 ± 29% after the first dose of metoprolol ($p < 0.037$), with no decrease during further dosing.

The changes in functional residual capacity, FEV_1, and FEF (25-75) induced by metoprolol were obliterated by the administration of aerosolized metaproterenol (Fig. 4). There were no differences in the groups when peak expiratory flow rates, airway resistance, specific conductance, thoracic gas volume, and total lung capacity were analyzed and compared. Arterial blood gases were unaffected by metoprolol therapy.

Despite the documented deterioration of FVC, FEV_1, and FEF (25-75), only 1 patient had clinically apparent deterioration of chronic airway obstruction (baseline FEV_1 33% of predicted) which required a decrease in metoprolol dosing to 100 mg/day and supplemental bronchodilator therapy.

Discussion

This study provides previously unavailable continuous ambulatory electrocardiographic monitoring data which document the efficacy of metoprolol in suppressing ventricular arrhythmias, and thus allow comparison to data available on other beta-blockers. Coltart et al[14,15] documented "significant" suppression of PVB at a plasma propranolol level of 40 to 85 ng/ml, a level which was also associated with significant beta blockade. Winkle et al[5] demonstrated at least a 75% reduction in PVB in 5 of 9 patients with mitral valve prolapse who were taking propranolol doses of 160 mg/day. Woosley et al[16] demonstrated a 70% suppression of PVB at a

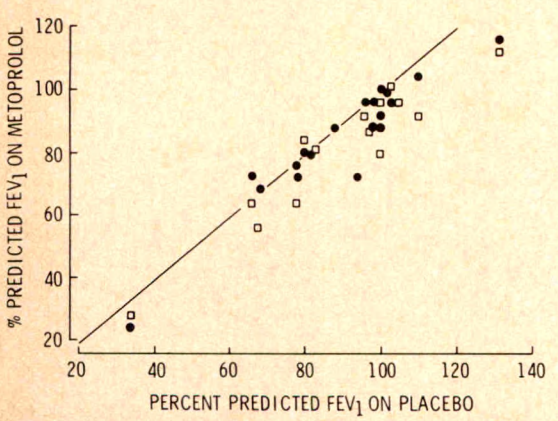

FIGURE 3. Percent change in FEV_1, placebo versus metoprolol before metaproterenol. FEV_1 = forced expiratory volume in 1 second. **Closed circles,** metoprolol, 100 mg/day; **open squares,** metoprolol, 200 mg/day.

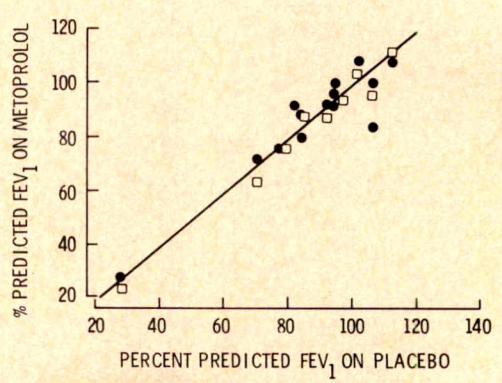

FIGURE 4. Percent change in forced expiratory volume in 1 second (FEV_1): placebo versus metoprolol after metaproterenol. **Closed circles,** metoprolol, 100 mg/day; **open squares,** metoprolol, 200 mg/day.

wide range of plasma propranolol levels (12 to 1,100 ng/ml). Interestingly, only one third of the patients responded at <160 mg/day of propranolol, while an additional 40% responded at propranolol doses of 200 to 640 mg/day. Thus, propranolol doses and plasma propranolol levels were frequently higher than comparable metoprolol doses in the present protocol. Propranolol has also been documented to suppress VT, especially if induced by exercise, a finding similar to the results of the present study.[3,17,18] Documentation of the ventricular antiarrhythmic effect of other beta-blockers, including tolamolol, alprenolol, and pindolol, lack studies utilizing long-term continuous ambulatory electrocardiographic recordings.[19–21] The duration of ambulatory electrocardiographic recording is crucial for appropriate evaluation of drug efficacy since recent studies emphasize a significant daily variability of ventricular arrhythmias.[22,23] In the present study, metoprolol at a dose of 100 mg/day suppressed only 34% of PVB, whereas 200 mg/day resulted in an overall 60% suppression of PVB. According to the data of Morganroth et al,[22] a 65% suppression of PVB is required to rule out variability as the cause of change in premature ventricular beat frequency in individual patients utilizing 3 days of placebo ambulatory electrocardiographic data and 3 days with the drug. By this criteria, high-dose metoprolol was "effective" in 50% of the 20 patients studied. The improved suppression of couplets (84%) and VT (94%), as well as abolition of exercise-induced VT, are all consistent with published observations of propranolol.[3,17]

This study also provides new information on plasma metoprolol levels achievable on routinely used dosage regimens as well as the degree of beta blockade demonstrated. High-dose metoprolol lowered the mean 24-hour heart rate from 78 to 62 beats/min while achieving a mean peak plasma metoprolol level of 72 ng/ml. This 20% decrease in the mean hourly heart rate during normal activity is similar to the 20 to 30% reduction in peak heart rate-blood pressure product documented by maximal exercise testing in this study. The wide range of peak plasma metoprolol levels (17 to 178 ng) obtained at steady-state doses of 200 mg daily are consistent with highly variable plasma propranolol levels[15,16] and emphasize the importance of clinical parameters to assess beta blockade. The lack of deterioration of resting left ventricular function or evidence for precipitation of clinical congestive heart failure even in patients with moderately depressed left ventricular function documents similar observations with other beta-blockers, even in the setting of acute myocardial infarction.[24–27,29] Experience from the National Beta-Blocker Heart Attack Trial demonstrated the ability of patients to tolerate significant doses of propranolol (160 to 320 mg/day) despite compensated congestive heart failure requiring digitalis and diuretics.[7] Similar observations were made during the Norweigan Metoprolol Trial, even with the use of intravenous metoprolol in the setting of acute myocardial infarction.[9]

Pulmonary function data were obtained because the use of metoprolol in many patients with obstructive lung disease may be desirable since the administration o nonselective beta-adrenergic blocking agents is pre cluded by bronchospasm. Several investigators hav documented the relatively cardioselective effects o metoprolol compared with propranolol in patients wit chronic bronchitis and asthma, although many reporte studies used single metoprolol doses. Tivenius,[28] how ever, found little effect of metoprolol on ventilator function in chronic airway obstruction after 4 doses o metoprolol; Formgren[29] documented a dose-relate effect on FEV_1 in asthmatic patients taking metoprolo who were studied over a 17-day interval.

The current study illustrates the spectrum of func tional ventilatory abnormalities that can be expecte in patients with cardiac disease receiving metoprolol i doses to achieve a peak mean plasma metoprolol leve of 72 ng/ml. We document the negative effects on FEV_1 FEF (25-75), and FVC, but emphasize that clinicall significant deterioration in ventilatory function occur only in a few select patients. The changes in FVC an FEV_1 are somewhat greater in our study than in report by McGavin and Williams[30] and Sinclair.[31] This ma be explained by our timing of pulmonary function test 2 hours after the test dose when drug levels are nea peak. These changes in FEV_1 and FVC could not b explained due to alterations in left ventricular functio with concomitant increase in lung water since there wa no evidence of further echocardiographic or clinical lef ventricular dysfunction with metoprolol.

Of the several patients who had measurable ob structive defects with decreasing FEV_1/FVC ratios an increasing airway resistance with metoprolol, only 1 ha clinically significant wheezing. With the exception o that patient's response, the group data suggest tha bronchodilator therapy obliterated these changes i FVC and FEV_1 induced by metoprolol. This furthe substantiates the findings of Thiringer and Svedmyr[3] and Johnson,[33] who reported that ventilatory change induced by metoprolol were readily reversed by beta adrenergic agonists but that those induced by pro pranolol were not. The availability of selective beta-adrenergic agonists such as albuterol may make con comitant therapy desirable, allowing the use of me toprolol when clinically indicated in these patients.

Our data further suggest that spirometry performe before and 2 hours after the first dose of metoprolol i useful to screen for pulmonary intolerance to beta blocking agents. A decrease in FVC or FEV_1 of >20 from baseline would mandate special caution and con stitute a relative contraindication to use of beta blockers. A decrease of 10 to 20% from baseline coul be corrected by the addition of a beta-2 selective agonis if the use of beta-blockers was indicated.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors of malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications**, **Warnings**, and **Precautions**.

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings**.

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

Writing with care for CHF:

Avoid any change in the classic digitalis-Lasix® regimen.

BRAND OF (furosemide)

9 out of 10 cardiologists specify LASIX® (furosemide) by brand name.* And 2 out of 3 take the extra step to prevent substitution.*

7 out of 10 cardiologists also specify the leading brand of digoxin.* Both are part of the classic LASIX®-digitalis regimen.

In the same survey,* LASIX® and the leading brand of digoxin were named more often than any other agent, in any therapeutic class, as drugs for which these cardiologists would *never* allow generic substitution. Both were prescribed by brand name more often than any other drug.

LASIX®—specified for good reason.

Especially in CHF, precision is crucial. Any therapeutic variable could easily upset the sensitive digitalis/diuretic/electrolyte balance and precipitate digitalis toxicity.

LASIX®, the most thoroughly documented drug in its class, offers quality so consistent that almost 8 billion tablets have been manufactured without a single product recall. In more dosage strengths and forms than any other diuretic. Good reason for the cardiologists surveyed to say they prescribe LASIX® more frequently than all other diuretic agents they named.

Before prescribing, please consult complete product information, a summary of which appears on the following page.

*National survey of 2960 physicians, including 1502 cardiologists and other physicians subspecializing in cardiology, conducted by Hoechst-Roussel Pharmaceuticals Incorporated, Somerville, New Jersey. August, 1982.

The diuretic of choice in CHF.

BRAND OF (FUROSEMIDE)

Rx

Specify LASIX® brand of furosemide. To be sure the patient receives only LASIX®, take the steps necessary on your prescription to prevent substitution, in accordance with the regulations of your state.

Lasix 40mg #60
Sig. 1 b.i.d.
Do Not Substitute

LASIX® (furosemide)

A brief summary of the Prescribing Information for Lasix (furosemide) Tablets 20, 40 and 80 mg.

WARNING: Lasix (furosemide) is a potent diuretic which, if given in excessive amounts, can lead to a profound diuresis with water and electrolyte depletion. Therefore, careful medical supervision is required, and dose and dose schedule have to be adjusted to the individual patient's needs.

INDICATIONS: Edema associated with congestive heart failure, cirrhosis of the liver, and renal disease, including the nephrotic syndrome. Hypertension when used alone or in combination with other antihypertensive drugs; patients not adequately controlled with thiazides also probably will not be adequately controlled with furosemide alone.

CONTRAINDICATIONS: Anuria. History of hypersensitivity to the compound.

WARNINGS: Excessive diuresis may result in dehydration and reduction in blood volume, with circulatory collapse and with the possibility of vascular thrombosis and embolism, particularly in elderly patients. Excessive loss of potassium in patients receiving digitalis glycosides may precipitate digitalis toxicity. Exercise care in patients receiving potassium-depleting steroids. Perform frequent serum electrolyte, CO_2, and BUN determinations during first few months of therapy and periodically thereafter, and correct abnormalities or temporarily withdraw the drug. Initial therapy of patients with hepatic cirrhosis and ascites is best carried out in the hospital. Closely observe cirrhotic patients for sudden fluid and electrolyte imbalances that may precipitate hepatic coma. Supplemental potassium chloride and, if required, an aldosterone antagonist are helpful in preventing hypokalemia and metabolic alkalosis. Discontinue furosemide if increasing azotemia and oliguria occur during treatment of severe, progressive renal disease. Observe patients regularly for possible blood dyscrasias, liver damage, or other idiosyncratic reactions. Patients with known sulfonamide sensitivity may show allergic reactions. Furosemide may potentiate the therapeutic effect of other antihypertensive agents. Potentiation occurs with ganglionic or peripheral adrenergic blocking drugs. Exacerbation or activation of systemic lupus erythematosus may occur. Furosemide appears in breast milk. If use of the drug is essential, the patient should stop nursing. Cases of tinnitus and reversible hearing impairment have been reported.

There have also been some reports of cases in which irreversible hearing impairment occurred. Usually ototoxicity has been reported when furosemide was injected rapidly in patients with severe impairment of renal function at doses exceeding several times the usual recommended dose and in whom other drugs known to be ototoxic were given. If the physician elects to use high-dose parenteral therapy in patients with severely impaired renal function, controlled intravenous infusion is advisable. (For adults, an infusion rate not exceeding 4 mg furosemide per minute has been used.)

PRECAUTIONS: As with any effective diuretic, electrolyte depletion may occur, especially in patients receiving higher doses and a restricted salt intake. Patients receiving furosemide should be observed for clinical signs of fluid or electrolyte imbalance, namely, hyponatremia, hypochloremic alkalosis, and hypokalemia. Serum and urine electrolyte determinations are particularly important when the patient is vomiting excessively or receiving parenteral fluids. Medication such as digitalis may also influence serum electrolytes. Hypokalemia may develop with furosemide as with any other potent diuretic, especially with brisk diuresis, when cirrhosis is present, or during concomitant use of corticosteroids or ACTH. Interference with adequate oral electrolyte intake will also contribute to hypokalemia. Digitalis may exaggerate metabolic effects of hypokalemia, especially with reference to myocardial activity. Asymptomatic hyperuricemia can occur and gout may rarely be precipitated. Increases in blood glucose and alterations in glucose tolerance tests with abnormalities of the fasting and two-hour postprandial sugar have been observed, and rare cases of precipitation of diabetes mellitus have been reported. Furosemide may lower serum calcium levels, and rare cases of tetany have been reported. Periodic serum calcium levels should be obtained. Reversible elevations of BUN may be seen. These have been observed in association with dehydration, which should be avoided, particularly in patients with renal insufficiency. Patients receiving high doses of salicylates in conjunction with furosemide may experience salicylate toxicity at lower doses because of competitive renal excretory sites. Furosemide has a tendency to antagonize the effects of tubocurarine and may potentiate the action of succinylcholine. Lithium generally should not be given with diuretics because they reduce its renal clearance and add a high risk of lithium toxicity. Diuretics such as furosemide may enhance the nephrotoxicity of cephaloridine. Therefore, furosemide and cephaloridine should not be administered simultaneously. Furosemide may decrease arterial responsiveness to norepinephrine. This diminution is not sufficient to preclude effectiveness of the pressor agent for therapeutic use. It has been reported in the literature that coadministration of indomethacin may reduce the natriuretic and antihypertensive effects of Lasix (furosemide) in some patients. This effect has been attributed to inhibition of prostaglandin synthesis by indomethacin. Indomethacin may also affect plasma renin levels and aldosterone excretion: this should be borne in mind when a renin profile is evaluated in hypertensive patients. Patients receiving both indomethacin and Lasix (furosemide) should be observed closely to determine if the desired diuretic and/or antihypertensive effect of Lasix (furosemide) is achieved.

PREGNANCY: Pregnancy Category C. Furosemide has been shown to cause unexplained maternal deaths and abortions in rabbits at 2, 4 and 8 times the human dose. There are no adequate and well-controlled studies in pregnant women. Furosemide should be used during pregnancy only if the potential benefit justifies the potential risk to the fetus.

ADVERSE REACTIONS: Anorexia, oral and gastric irritation, nausea, vomiting, cramping, diarrhea, constipation, jaundice (intrahepatic jaundice), pancreatitis, dizziness, vertigo, paresthesias, headache, xanthopsia, blurred vision, tinnitus and hearing loss, anemia, leukopenia, agranulocytosis (rare), thrombocytopenia, aplastic anemia (rare), purpura, photosensitivity, rash, urticaria, necrotizing angiitis (vasculitis, cutaneous vasculitis), exfoliative dermatitis, erythema multiforme, pruritus. Orthostatic hypotension may occur and may be exaggerated by alcohol, barbiturates, or narcotics. Other adverse reactions include hyperglycemia, glycosuria, hyperuricemia, muscle spasm, weakness, restlessness, urinary bladder spasm, thrombophlebitis.

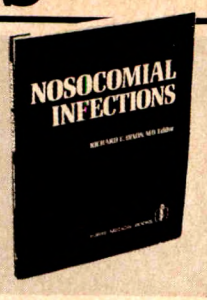
$29.50 hardbound
ISBN 0-914316-24-9
$19.50 softbound
ISBN 0-914316-29-X



Based on the proceedings of the 2nd International Conference on Nosocomial Infections held August 5 - 8, 1980 in Atlanta, Georgia and sponsored by the Center for Disease Control, this book provides between two covers the most comprehensive, in-depth study of this international problem published in 10 years. This major reference is divided into 11 sections consisting of 50 chapters written by over 100 internationally known experts.

The book includes:

- An update of disease trends since the 1st International Conference held a decade earlier
- New information on the efficacy of specific approaches to infection control
- Discussions on how to implement effective infection surveillance and control programs
- Coverage of the increasing importance of antimicrobial resistance of nosocomial pathogens
- Information on the potential usefulness of antimicrobial prophylaxis in selected patient groups

and many other topics.

MYTH: Catheter-tip pressure transducers are too fragile for *routine* use.

FACT: Not any more. Advanced semiconductor technology makes the MIKRO-TIP® Catheter Pressure Transducer durable . . . so durable it can be used *routinely* again and again and again.[1]

It's true that catheter-tip pressure transducers are not suitable for every pressure measurement situation. However, when accurate patient diagnosis is at stake, the Millar MIKRO-TIP® transducer, now with the MT-10™ pressure sensor, should be your only choice for patient blood pressure measurements.

Using the latest advances in semiconductor technology, we made the MT-10™ pressure sensor several times more impact resistant than previous sensors. It is insensitive to ambient light and to changes in temperature and provides accurate high fidelity measurements with exceptional baseline stability. In addition to its durability, transducers with the new MT-10™ pressure sensor have all the excellent features of our previous transducers, such as good linearity, negligible hysteresis, large output signal with good signal-to-noise ratio, and high frequency response for the detection of intracavitary sounds.

The MT-10™ is now the standard pressure sensor in all Millar MIKRO-TIP® transducers, size 5F (1.7 mm o.d.) and larger. In *routine* use around the world, the MT-10™ pressure sensor is setting the standard in durability for all catheter-tip pressure transducers.

Today your best choice for patient blood pressure measurement is the Millar MIKRO-TIP® Catheter Pressure Transducer, **and that's a fact.** Call your Millar representative today for an informative videotape presentation of the MIKRO-TIP® Catheter Pressure Transducer in clinical use.

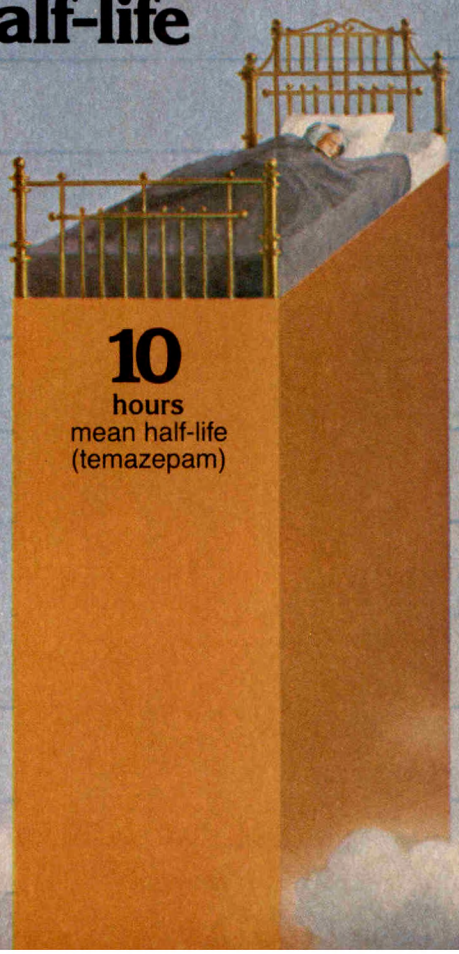
C IV

15 mg
30 mg
capsules

(temazepam)

RESTORIL®
(temazepam)
has an appropriate half-life



A half-life (mean of 10 hours) that parallels normal sleep time:

- patient gets 7-8 hours sleep
- most medication gone by morning
- patient awakes alert and refreshed
- minimal side effects•
- insignificant accumulation

Please see brief summary of prescribing information on next page.

Restful sleep, alert awakening

R[illegible]T-RIL® C IV 15 mg 30 mg capsules

(temazepam)

A more appropriate half-life

One 30-mg capsule, h.s.—*usual adult dosage.*
One 15-mg capsule, h.s.—*recommended initial dosage for elderly and/or debilitated patients.*

INDICATIONS AND USAGE: Restoril® (temazepam) is indicated for the relief of insomnia associated with complaints of difficulty in falling asleep, frequent nocturnal awakenings, and/or early morning awakenings. Since insomnia is often transient and intermittent, the prolonged administration of Restoril is generally not necessary or recommended. Restoril has been employed for sleep maintenance for up to 35 consecutive nights of drug administration in sleep laboratory studies.

The possibility that the insomnia may be related to a condition for which there is more specific treatment should be considered.

CONTRAINDICATIONS: Benzodiazepines may cause fetal damage when administered during pregnancy. An increased risk of congenital malformations associated with the use of diazepam and chlordiazepoxide during the first trimester of pregnancy has been suggested in several studies. Also, ingestion of therapeutic doses of benzodiazepine hypnotics during the last weeks of pregnancy has resulted in neonatal CNS depression. Restoril is contraindicated in pregnant women. Consider a possibility of pregnancy when instituting therapy or whether patient intends to become pregnant.

WARNINGS: Patients receiving Restoril (temazepam) should be cautioned about possible combined effects with alcohol and other CNS depressants.

PRECAUTIONS: In elderly and/or debilitated patients, it is recommended that initial dosage be limited to 15 mg. The usual precautions are indicated for severely depressed patients or those in whom there is any evidence of latent depression; it should be recognized that suicidal tendencies may be present and protective measures may be necessary.

If Restoril is to be combined with other drugs having known hypnotic properties or CNS-depressant effects, due consideration should be given to potential additive effects.

Information for Patients: Patients receiving Restoril should be cautioned about possible combined effects with alcohol and other CNS depressants. Patients should be cautioned not to operate machinery or drive a motor vehicle. They should be advised of the possibility of disturbed nocturnal sleep for the first or second night after discontinuing the drug.

Laboratory Tests: The usual precautions should be observed in patients with impaired renal or hepatic function. Abnormal liver function tests as well as blood dyscrasias have been reported with benzodiazepines.

Pregnancy: Pregnancy Category X. See Contraindications.

Pediatric Use: Safety and effectiveness in children below the age of 18 years have not been established.

ADVERSE REACTIONS: The most common adverse reactions were drowsiness, dizziness and lethargy. Other side effects include confusion, euphoria and relaxed feeling. Less commonly reported were weakness, anorexia and diarrhea. Rarely reported were tremor, ataxia, lack of concentration, loss of equilibrium, falling and palpitations. And rarely reported were hallucinations, horizontal nystagmus and paradoxical reactions, including excitement, stimulation and hyperactivity.

Restoril is a controlled substance in Schedule IV. Caution must be exercised in addiction-prone individuals or those who might increase dosage.

DOSAGE AND ADMINISTRATION: *Adults:* 30 mg usual dosage before retiring; 15 mg may suffice in some. *Elderly and/or debilitated:* 15 mg recommended initially until individual response is determined.

SUPPLIED: Restoril (temazepam) capsules—15 mg maroon and pink, imprinted "RESTORIL 15 mg"; 30 mg, maroon and blue, imprinted "RESTORIL 30 mg". Packages of 100, 500 and ControlPak® packages of 25 capsules (continuous reverse-numbered roll of sealed blisters). (RES-Z2 11/1/81)

Before prescribing, see package insert for full product information.

Pacemaker system currently undergoing clinical evaluation.

Indications: Diplos is a two channel pacemaker intended for permanent two-chamber cardiac pacing.

Contraindications. Some stimulation modes may be contraindicated in some patients. Consult the technical manual for detailed information.

Side effects. The following is a list of side effects which

of pulse generator: transvenous lead-related thrombosis and cardiac tamponade.

Warnings. Diathermy should not be used on patients with implanted pacemakers. The use of electrosurgical instruments in the presence of unipolar pulse generators must be avoided. If the paddles of a defibrillator are placed over

Precautions. An implanted pacemaker may fail at any time due to unpredictable battery or other random component failures. Furthermore problems caused by leads, e.g. displacement, fracture, fibrotic tissue, raised threshold, can stop pacing at any time. Electrical interference may effect the correct operation of an implanted pacemaker.

Syncope and Ventricular Tachycardia in Patients With Ventricular Preexcitation

ELWYN A. LLOYD, MD, RICHARD N. HAUER, MD, DOUGLAS P. ZIPES, MD, JAMES J. HEGER, MD, and ERIC N. PRYSTOWSKY, MD

Four patients with ventricular preexcitation whose syncope initially was attributed to an arrhythmia utilizing the accessory pathway are presented. At electrophysiologic study, the electrophysiologic characteristics of the accessory pathways were considered unlikely to support a tachycardia of a rate sufficient to result in syncope. Programmed stimulation of the right ventricle, however, reproducibly induced ventricular tachycardia to which the syncope was subsequently attributed in 3 patients. The importance of identifying ventricular tachycardia as the cause of syncope in these patients is emphasized.

Patients who have ventricular preexcitation may present with syncope which often is assumed to be related to an arrhythmia utilizing the accessory pathway. Atrial fibrillation (AF) with a rapid ventricular response due to conduction over an accessory pathway is probably the most common cause of syncope in these patients, although a rapid atrioventricular reciprocating tachycardia also may cause a decrease in cardiac output and loss of consciousness. In older patients with cerebrovascular disease in whom minor reductions in cardiac output can reduce cerebral perfusion significantly and in patients with impaired myocardial function, relatively slower supraventricular tachycardia rates may result in syncope or presyncope. Ventricular tachycardia (VT) often causes syncope, but the occurrence of VT in patients with ventricular preexcitation rarely has been documented by electrophysiologic study.[1,2] We present 4 patients with accessory pathways who at electrophysiologic study had VT induced, which was considered to be the cause of neurologic symptoms in 3 patients.

Methods

After admission to a cardiac care unit where their cardiac rhythms were monitored continuously, all patients underwent electrophysiologic study in the drug-free control state after giving written informed consent. Three or 4 multipolar electrode catheters were introduced percutaneously into the femoral, subclavian, or antecubital veins and positioned under fluoroscopic guidance in the high right atrium, across the tricuspid valve in the region of the His bundle, in the right ventricular apex, and in the coronary sinus. Intracardiac recordings filtered at 30 to 500 Hz and standard electrocardiographic leads I, II, III, and V_1 filtered at 0.1 to 20 Hz were displayed simultaneously on an Electronics for Medicine VR-12 multi-channel oscilloscope and recorded at paper speeds of 50 to 150 mm/s. Pacing was performed with a custom built programmable stimulator (MECA) using 2.0 ms rectangular pulses at twice late diastolic threshold.

Our pacing protocol to study the electrophysiologic properties of accessory pathways and to initiate supraventricular and ventricular tachycardias has been described in detail.[3,4] In brief, the right or left atrium (or both) was paced at progressively faster rates until atrioventricular block occurred; premature right atrial and coronary sinus stimulation was performed at ≥2 cycle lengths. Programmed right ventricular stimulation during sinus rhythm and right ventricular pacing at 3 cycle lengths (600, 500, and 400 ms) was carried out using 1 and 2 extrastimuli at various coupling intervals.

VT was defined as nonsustained when it lasted <30 seconds and did not cause hemodynamic deterioration requiring termination.

Patients: All 4 patients were men in whom the resting electrocardiogram revealed ventricular preexcitation (Table I). They were referred for further evaluation of syncope (3 cases) or presyncope (1 case) attributed to an arrhythmia utilizing the accessory pathway. In 2 patients (Patients 1 and 4), a wide QRS complex tachycardia had been recorded at the time of syncope but was unavailable for our inspection.

Patients 1 and 3 had no evidence of structural heart disease observed on physical examination, chest roentgenography, exercise stress test, and echocardiography, and patient 1 had normal coronary arteries and left ventricular function defined by cardiac catheterization. Patient 2 had a history of hypertension and a thickened left ventricle documented by echocardiography. He had no history of chest pain and a normal exercise stress test. Patient 4 had a previous myocardial infarction and total obstruction of the left anterior descending coronary artery associated with an anteroapical aneurysm noted at cardiac catheterization.

TABLE I Patient Characteristics

Patient	Age (yr)	Heart Disease	Symptoms			Treatment	Follow-Up Symptoms
			Presenting	Frequency	Duration		
1	22	None	Syncope	2 episodes	2 weeks	Encainide	5 months, none
2	47	Hypertensive	Syncope	Twice weekly	10 years	Procainamide	12 months, palpitations, presyncope
3	30	None	Presyncope	Daily	1 month	Quinidine	13 months, none
4	50	CAD	Syncope	5 episodes	4 years	None	18 months, none, CHF

CAD = coronary artery disease; CHF = congestive heart failure.

TABLE II Electrophysiologic Characteristics

Patient	Location of Pathway	Shortest PCL With 1:1 Anterograde Conduction Over AP (ms)	Anterograde ERP of AP at PCL (600 ms)	Shortest R-R During A Fib (ms)	Mean R-R During A Fib (ms)	Shortest PCL Maintaining 1:1 Conduction Retrograde (ms)	Mode of VT Induction*	Mean Cycle Length of VT (ms)
1	Left-lateral	330	290	310	500	VA block	V_2V_3 (500, 400 ms)	170
2	Right-† lateral	310	290	Not inducible	Not inducible	VA block	V_2V_3 (400 ms)	220
3	Right-anterior-paraseptal	<250	300	270	380	270	A_2;V_2V_3 (600,500 ms)	240
4	Left-posterior	>870	>600	Not inducible	Not inducible	540	V_2V_3 (500, 400 ms)	275

* Pacing cycle length is given in parentheses.
† This patient also had an accessory fasciculoventricular connection.
A_2 = 1 atrial extrastimulus introduced during normal sinus rhythm; A Fib = atrial fibrillation; AP = accessory pathway; ERP = effective refractory period; PCL = pacing cycle length; V_2V_3 = 2 ventricular extrastimuli introduced during ventricular pacing; VA = ventriculoatrial; VT = ventricular tachycardia.

Results

Atrioventricular reciprocating tachycardia could not be induced in any of the patients despite programmed electrical stimulation at multiple pacing cycle lengths in the right atrium, coronary sinus, and right ventricle. The electrophysiologic data of all 4 patients are shown in Table II. Nonsustained VT was induced in all patients using 2 premature stimuli while pacing the right ventricle. Patient 1 had presyncope during the induced VT (Fig. 1). In patient 3, nonsustained VT also was induced by an atrial extrastimulus during sinus rhythm (Fig. 2).

Patients 1 and 2 had complete ventriculoatrial block in the accessory pathway and in the normal ventriculoatrial conduction system (Fig. 3). In Patient 3 ventricular pacing resulted in a normal retrograde atrial activation sequence and ventriculoatrial conduction was maintained to a cycle length of 270 ms with no increase in the ventriculoatrial interval at the shortest pacing cycle length. These combined findings suggest retrograde conduction over a septal accessory pathway, but do not exclude retrograde conduction over the normal ventriculoatrial conduction system.[5] In Patient 4 ventriculoatrial block occurred while pacing the ventricle at a cycle length of 540 ms.

In Patient 2, the presence of an accessory fasciculoventricular pathway in addition to an accessory atrioventricular pathway was demonstrated (Fig. 4). The short H-V interval remained constant throughout multiple catheter positions at the His bundle area.

Follow-up (Table I): Patient 1 underwent serial electrophysiologic testing; encainide therapy prevented initiation of VT and he has had no recurrence of symptoms. Patient 2 was given procainamide that abolished anterograde conduction over the accessory pathway but did not prevent VT induction at electro-

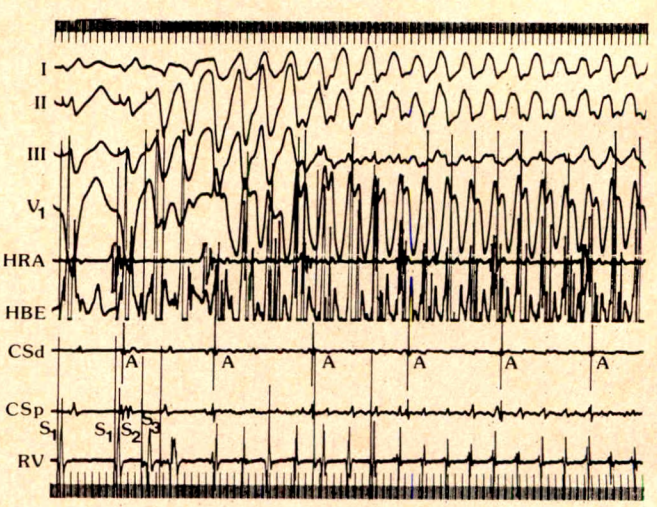

FIGURE 1. Induction of ventricular tachycardia at a rate of 353 beats/min (Patient 1). The top 4 tracings are electrocardiographic leads I, II, III, and V_1. The bottom 5 tracings are electrograms recorded from catheters in the high right atrium (HRA), His bundle area (HBE), distal coronary sinus (CSd), proximal coronary sinus (CSp), and right ventricular apex (RV). The right ventricle is being paced (S_1-S_1 400 ms); 2 premature stimuli (S_2-S_3) are introduced resulting in rapid monomorphic ventricular tachycardia at a mean cycle length of 170 ms. The CSd electrogram demonstrates ventriculoatrial dissociation. Time lines = 50 ms/major division.

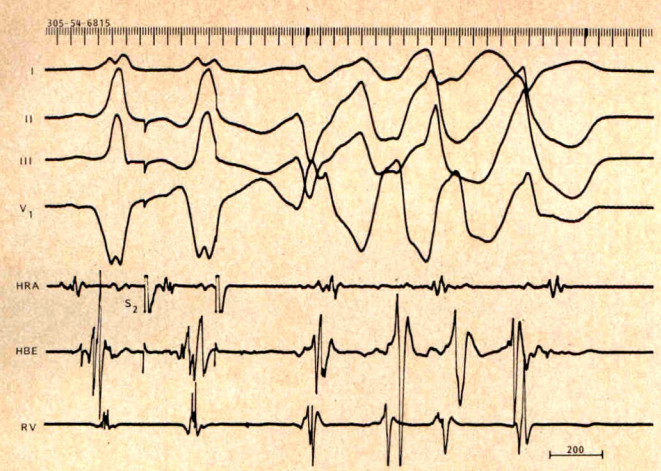

FIGURE 2. Induction of ventricular tachycardia during atrial premature stimulation. An atrial extrastimulus (S_2) with a coupling interval of 330 ms conducts to the ventricle over the accessory pathway and initiates nonsustained ventricular tachycardia. A second stimulus artifact 270 ms after S_2 fails to capture the atrium. Abbreviations as in Figure 1.

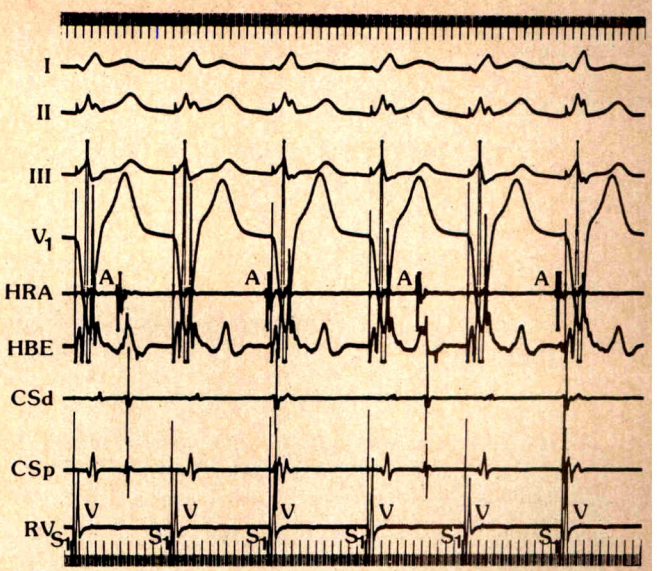

FIGURE 3. Complete retrograde block (Patient 1). The right ventricle is being paced (S_1) at a cycle length of 600 ms, there is ventriculoatrial dissociation, the atrial complexes (A) occurring regularly at a cycle length of 900 ms. Abbreviations as in Figure 1.

physiologic study. He refused further testing, was discharged taking procainamide, and has monthly episodes of presyncope and palpitations. Patient 3 was treated empirically with quinidine. Ventricular preexcitation was unaffected but the patient was asymptomatic for 13 months of follow-up study. Of note, palpitations occurred when the patient voluntarily stopped taking quinidine. Patient 4 did not want to take antiarrhythmic drugs and has had no recurrence of syncope but developed congestive heart failure. It should be noted that at least 2 of his syncopal episodes were associated with heavy alcohol consumption, and it is not clear that VT was responsible for his episodes of syncope.

Discussion

The electrophysiologic properties of 322 patients with ventricular preexcitation combined from 2 reports reveal that only 2 had VT independent of their accessory pathways,[1,2] confirming that this is a rare occurrence. It clearly is important to identify those patients whose syncope is caused by ventricular tachycardia and not by reciprocating tachycardia using the accessory pathway as part of the reentrant circuit or AF with a rapid ventricular response over the accessory pathway, for the treatment of these various arrhythmias may differ.

In patients with ventricular preexcitation and an accessory pathway with a short anterograde effective refractory period, the occurrence of AF may result in very rapid ventricular rates due to conduction over the accessory pathway. This may produce syncope and

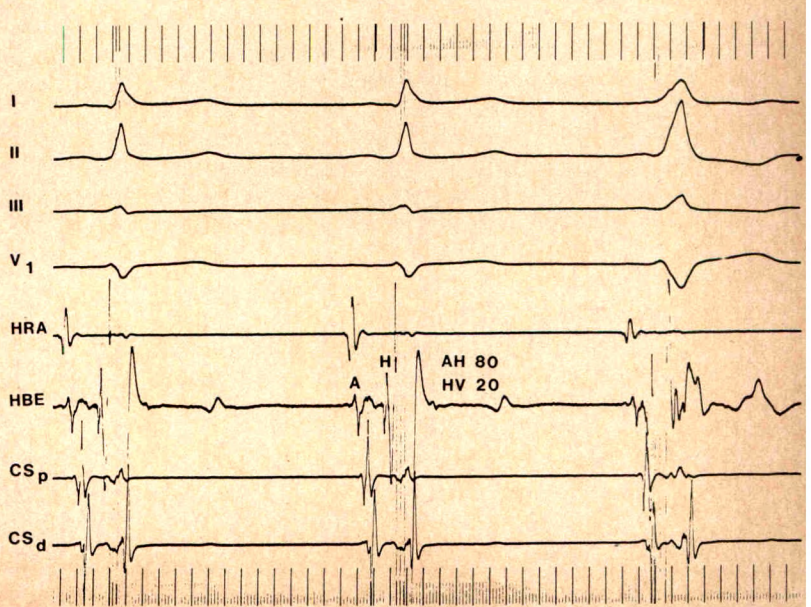

FIGURE 4. Atrioventricular and fasciculoventricular accessory pathways (Patient 2). The first 2 complexes demonstrate an H-V interval of 20 ms which persisted throughout the study, confirming the presence of an accessory fasciculoventricular pathway. This was the longest H-V interval recorded throughout the study. In the third complex, the His deflection is buried in the QRS complex while the surface electrocardiogram demonstrates ventricular preexcitation, confirming the presence of an accessory atrioventricular connection.

possible degeneration of the rapid rhythm into ventricular fibrillation (VF). It has been observed that the shortest R-R interval during AF in 14 of 18 such patients with VF was <205 ms.[2] In Patients 1 and 3, in whom AF was induced, the shortest R-R interval was 310 and 270 ms, respectively. This observation is consistent with the conclusion that VF resulting from a rapid ventricular response to AF was not the cause of the syncope in these 2 patients. Furthermore, the mean R-R interval during AF in these 2 patients was 500 and 380 ms, respectively, cycle lengths unlikely to have resulted in syncope in these 2 young, otherwise healthy persons.

In Patients 2 and 4, AF could not be induced and therefore could not be excluded as a cause of their syncope. However, the relation between the effective refractory period of the accessory pathway in the anterograde direction and the shortest R-R interval during AF has been demonstrated to be linear.[6] Applying these data[6] to Patients 2 and 4, whose effective refractory periods of the accessory pathway in the anterograde direction were 290 and >600 ms, respectively, the shortest R-R interval in response to AF would have been on the order of 290 and 600 msec, respectively, which is considerably longer than the shortest R-R interval of those patients who had VF.[2] In a second study,[7] all but 2 of 21 patients who had VF had anterograde effective refractory periods of the accessory pathway <290 ms. It is therefore unlikely that AF would have resulted in VF in these patients.

In addition to allowing a rapid ventricular response to AF or flutter, accessory pathways may lead to syncope by participating in the circuit of an atrioventricular reciprocating tachycardia, if the rate is fast enough. However, the inability to induce reciprocating tachycardia in the laboratory in these 4 patients despite programmed stimulation at multiple sites and cycle lengths makes this mechanism of syncope highly improbable.[8] Thus, the electrophysiologic data of these patients suggest that the accessory pathway was incapable of participating in an arrhythmia that would have caused sufficient hemodynamic disturbance to result in syncope.

Although the induced VT in these 4 patients as the cause of syncope is not entirely proven, 2 of them had a wide QRS complex tachycardia documented at the time of syncope; the electrophysiologic data indicate that this is not likely to have been the result of AF conducted over the accessory pathway. Furthermore, ventricular tachycardia induced by programmed electrical stimulation using only 1 or 2 extrastimuli and not isoproterenol or left ventricular stimulation suggests that the arrhythmia occurs clinically[9–11] and the incidence of false-positive findings in patients without structural heart disease, using these stimulation techniques, is very low.[12] In Patients 1 and 3, therefore, there is good evidence that VT was the cause of their syncope. However, more recent data suggest that VT can be induced in patients with coronary artery disease but without a history of VT.[13] Thus, VT induced in Patient 4 may have been a false-positive result.

Although only nonsustained VT was induced at electrophysiologic study in Patient 2, we feel that his clinical symptoms were due to more prolonged episodes of VT. It is not always possible to induce sustained ventricular tachycardia using the aforementioned techniques (Methods) in patients who have electrocardiographically proven sustained VT as we[14] have previously published. Further, although procainamide therapy has abolished anterograde accessory pathway conduction, the patient remains symptomatic.

Addendum

We recently performed an electrophysiologic study on a 41-year old-woman with Wolff-Parkinson-White syndrome but with no other identifiable structural heart disease. She had a history of 4 syncopal attacks, 2 resulting in fractures of her arm and leg. The electrocardiogram showed ventricular preexcitation in sinus rhythm, but no conduction occurred over the accessory pathway during AF initiated during electrophysiologic study. Ventriculoatrial dissociation occurred at all ventricular pacing cycle lengths. Multiple episodes of nonsustained VT were induced during ventricular pacing at a cycle length of 600 ms using 2 extrastimuli. The tachycardia cycle length was 220 ms (272/min), and 1 episode resulted in loss of consciousness before spontaneous termination. This patient's symptoms cannot be explained by arrhythmias involving the accessory pathway, and are most likely due to VT.

Efficacy, Safety, and Pharmacokinetics of a Concentration-Maintaining Regimen of Intravenous Pirmenol

MICHAEL J. REITER, MD, PhD, STEPHEN C. HAMMILL, MD, DAVID G. SHAND, MB, PhD, CHAKO VERGHESE, MD, ELIZABETH McCARTHY, RN, and EDWARD L. C. PRITCHETT, MD

A 3-stage, concentration-maintaining intravenous infusion regimen of pirmenol, a new antiarrhythmic agent, was tested for efficacy and safety in 8 subjects with chronic, stable premature ventricular beats. The regimen, which consisted of (1) a priming bolus of 50 mg over 2 minutes, followed by (2) a rapid loading infusion of 2.5 mg/min for 1 hour, and (3) a maintenance infusion of 0.25 mg/min, rapidly achieved and maintained stable plasma pirmenol levels from 0.94 to 2.75 μg/ml, during infusions lasting up to 48 hours. Therapeutic efficacy was evaluated during 4-hour infusions in 5 patients utilizing a randomized, double-blind, placebo-controlled study design. Pirmenol suppressed average premature ventricular beat frequency 93 ± 6% compared with control values (p = 0.03). Pirmenol infusions were unassociated with toxicity. There were slight but significant increases in diastolic blood pressure, QRS duration, and corrected Q-T interval. No significant changes occurred in systolic blood pressure, heart rate, P-R interval, or laboratory variables. Pirmenol is a promising therapeutic agent that warrants further evaluation. The 3-stage infusion satisfactorily achieves and maintains therapeutic plasma pirmenol levels.

Pirmenol (Parke-Davis, CI-845) is a new antiarrhythmic agent which has electrophysiologic properties similar to class I antiarrhythmic drugs in canine Purkinje fibers.[1] Recently, the promising canine experience[2,3] was confirmed in the first reported human studies.[4,5] In 10 subjects, 70 to 150 mg of pirmenol was administered intravenously over 30 minutes at a constant rate. Peak plasma concentrations of 1.0 to 3.8 μg/ml were produced and caused ≥90% reduction in the frequency of chronic, stable, premature ventricular beats (PVBs) in 9 of 12 instances.[4] To be clinically useful, however, intravenous pirmenol will have to be administered by an infusion regimen that rapidly achieves and maintains stable plasma concentrations. An intravenous loading and maintenance regimen has been devised using pharmacokinetic parameters calculated from the 30-minute infusions.[6] This study describes the efficacy and safety of this regimen during infusions of 4 to 48 hours in patients with PVBs.

Methods

Subjects: A total of 8 subjects (7 men and 1 woman; mean age 54 years, range 38 to 66) with chronic stable PVBs were studied. Subjects had a mean of 960 ± 615 PVBs/hour during the control period before infusion. No subject had sustained tachycardia, sinus nodal abnormality, or conduction system delay. No person with a history of acute myocardial infarction within the previous 6 months or with severe chronic obstructive pulmonary disease were included. All antiarrhythmic drugs were discontinued at least 4 half-lives before study. Six subjects received intravenous pirmenol or placebo on successive study days (separated by a rest day) using a randomized, double-blind, crossover study design. Four of these subjects and 2 other subjects received open-label pirmenol as a prolonged infusion of 8 to 48 hours. Five subjects had previously received pirmenol in our earlier study.[4]

Four subjects had definite or probable coronary artery disease (2 had a history of myocardial infarction). Two other subjects had a history of moderate hypertension (1 of whom also had diabetes mellitus of adult onset). Two subjects had no apparent cardiac disease. No subjects had symptoms of congestive heart failure. Cardiothoracic index was ≤0.54 for all subjects (mean 0.48). Baseline 2-dimensional and M-mode

echocardiography was normal in 7 subjects and revealed mild septal hypokinesia in 1 person.

The following tests performed in all subjects before and after pirmenol infusion: 12-lead electrocardiogram, complete blood count, reticulocyte count, prothrombin time, serum electrolytes, glucose, total protein, total bilirubin, serum glutamic oxaloacetic transaminase, serum glutamic pyruvate transaminase, lactic dehydrogenase, alkaline phosphatase, creatinine, blood urea nitrogen, fluorescent antinuclear antibody, creatinine phosphokinase, and urinalysis.

Pirmenol administration: The method for simulation of the plasma pirmenol concentration after complex dosage regimen has been fully described in a previous publication.[6] It involves utilizing the pharmacokinetic parameters derived from single-dose infusions. These parameters are then used to separately calculate the plasma concentration versus time curves for the priming bolus, the loading infusion, and the maintenance infusion which are then summed to yield a simulation of the dosage regimen. To design the final regimen, somewhat arbitrary decisions about the duration of the rapid loading infusion (1 hour) and maximum level after loading (2.5 μg/ml) were made.

The final regimen was a 3-stage dosing regimen consisting of (1) a priming bolus of 50 mg delivered over 2 minutes, followed by (2) a rapid loading infusion of 2.5 mg/min for 1 hour, and finally (3) a maintenance infusion of 0.25 mg/min. The rapid loading and maintenance infusions were obtained from a concentration of 2.5 mg of pirmenol per milliliter of sterile isotonic saline solution delivered at rates of 60 and 6 ml/hour, respectively, by a gravity fed controller (IVAC 230) through a 20 gauge Teflon® cannula inserted into a superficial arm vein.

Blood samples for pirmenol assay were obtained from another 20 gauge cannula in the opposite arm.

Electrocardiographic monitoring: All subjects were studied in normal sinus rhythm while resting and supine. Continuous electrocardiographic monitoring of a modified lead II (left shoulder negative, cardiac apex positive) was performed for 1 hour before, during, and for 4 hours after drug infusion using a Hewlett-Packard model 78100A and 78101A telemetry transmitter and receiver and an Elema Mingograf ink jet recorder. In addition, the coronary care unit staff monitored each subject's electrocardiogram continuously during drug infusion. A staff cardiologist determined the frequency of PVBs per half-hour period by manual analysis during both the double-blind protocol and prolonged infusions. Electrocardiographic intervals (P-R interval, QRS duration, and Q-T interval) were recorded at a paper speed of 100 mm/s at 30 minute intervals for the first 4 hours of drug infusion and then at 2 hourly intervals during prolonged pirmenol infusions. Blood pressure was determined by the cuff method.

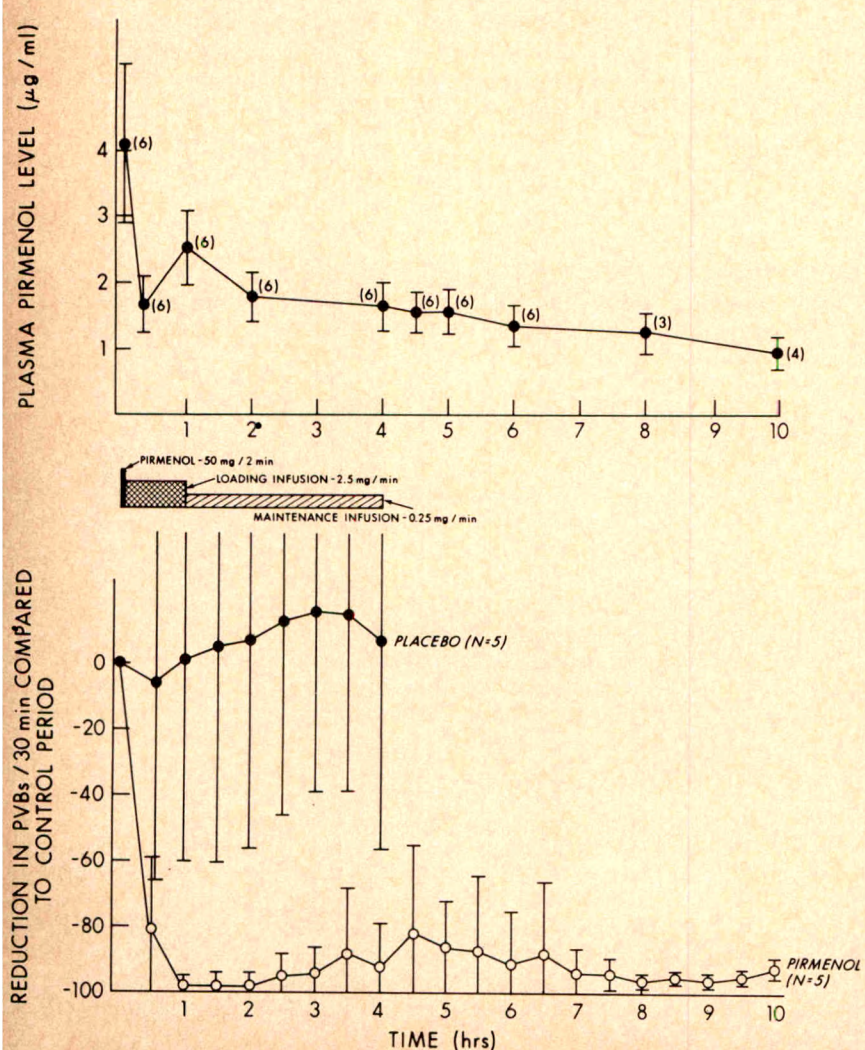

FIGURE 1. Mean plasma pirmenol concentration (**top**) and reduction in premature ventricular beat (PVB) frequency (**bottom**) during and after 4-hour infusions of pirmenol are shown. PVB frequency during placebo infusion is also shown. Pirmenol levels (mean ± standard deviation) represent data from 6 subjects participating in the double-blind placebo-controlled trial. One subject was excluded from analysis of PVB frequency when he failed to meet the inclusion criteria of at least 1 PVB/min during the lead-in control periods of both infusion days.

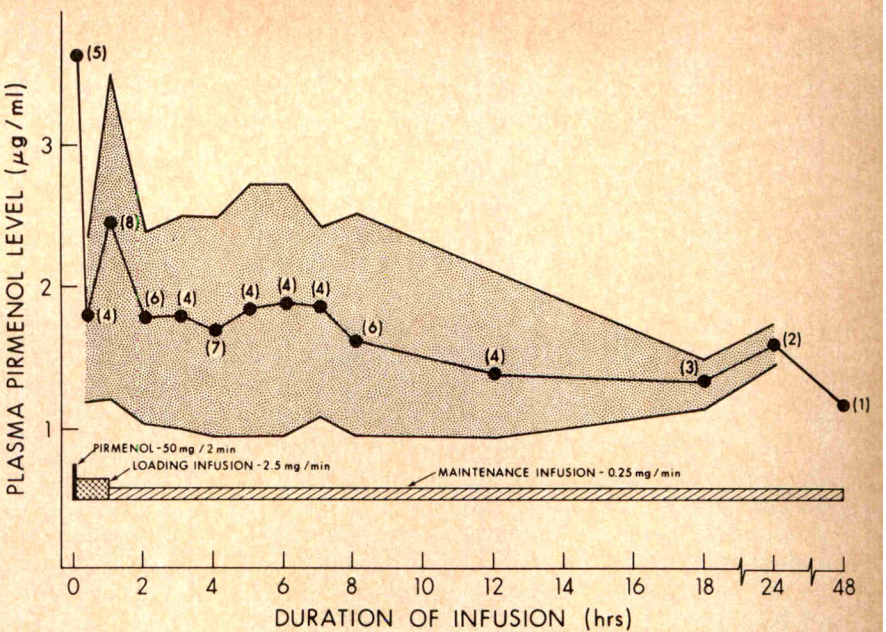

FIGURE 2. Mean and range of plasma pirmenol concentration are shown during the concentration-maintaining intravenous infusion. Mean values were determined from 1 infusion for each of the 8 subjects. Number of subjects for whom data were available at each time is shown in parentheses. Range of plasma pirmenol levels represent extremes observed during all 12 infusions (4 subjects received both a 4-hour infusion on double-blind study days and an open-label infusion for ≥8 hours).

Pirmenol assay: Blood samples were placed in heparinized glass tubes and immediately centrifuged. The plasma was separated, frozen, and stored at −20°C until assay. Pirmenol concentration in plasma was measured using a previously described high performance liquid chromatographic technique.[7] Efficiency of the extraction technique was 70 ± 1.5%. The method was sensitive to approximately 0.1 μg/ml of pirmenol with a coefficient of variation of 7%.

Statistical analysis: For the analysis of drug efficacy during the double-blind, crossover protocol, the quantity R = mean log (PVBs per half-hour + 1) for each half-hour of the 4-hour treatment period (8 half-hour periods) − mean log (PVBs per half-hour + 1) of the average for the 30-minute control periods was computed for each of the 2 study days for each subject. R measures the response during the infusion period with respect to baseline for that day. The difference R (pirmenol) minus R (placebo) was calculated for each subject and the differences were tested for their median being zero using the Wilcoxon signed-rank test. This analysis controls for day-to-day variability in PVB frequency.

Differences in blood pressure, heart rate, and electrocardiographic intervals were also compared using the Wilcoxon signed-rank test.

Results

Effect of pirmenol on PVB frequency: During the double-blind protocol, 1 of the 6 subjects failed to meet the inclusion criteria of at least 1 PVB/min during both control periods and was excluded from analysis of efficacy. In the remaining 5 patients, the effect of pirmenol was apparent within minutes after the priming injection. Average PVB frequency was reduced 93 ± 6% during the infusion of pirmenol (Fig. 1). Placebo infusion was associated with a slight increase in PVB frequency (+7 ± 7%). This difference was statistically significant ($p = 0.03$, $n = 5$). Four of 5 subjects had ≥90% reduction in PVBs throughout the infusion. One subject had nearly complete suppression of PVBs for the first 2 hours of pirmenol infusion and then had a return of ectopy; in this subject, PVB frequency was reduced 48% for the 4-hour infusion.

A ≥90% reduction in PVBs persisted for approximately 6 hours after the end of the pirmenol infusion, at which point plasma pirmenol concentration was 0.95 ± 0.24 μg/ml (n = 4).

In 4 subjects who received prolonged pirmenol infusions, PVB frequency was reduced 94 ± 5% during the fourth through the eighth hours of the infusion. Suppression of ectopy was complete and maintained throughout the infusion for the 2 subjects who received pirmenol infusions of 18 and 48 hours.

Plasma pirmenol levels: The 8 subjects received 12 separate infusions of pirmenol for 4 to 48 hours (Fig. 2), including double-blind and open-label study days. Plasma pirmenol levels immediately after completion

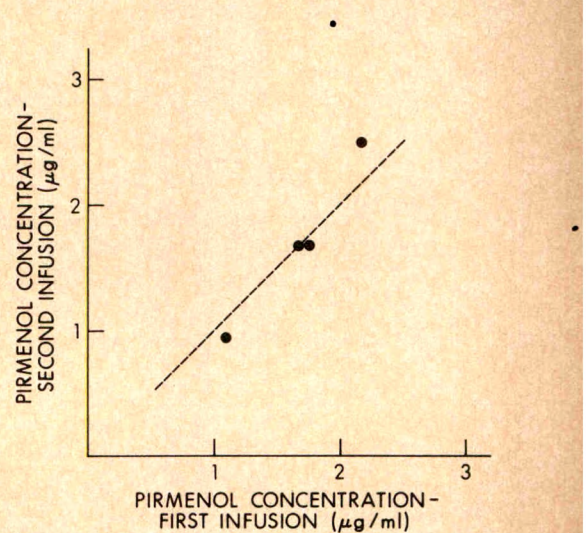

FIGURE 3. Intrasubject variability of plasma pirmenol concentration for the 4 subjects who received 2 separate infusions is shown. Pirmenol concentrations after 4 hours of infusion are compared. The line of identity is also shown.

of the 50 mg bolus injection averaged 3.41 μg/ml but were very variable (range 2.25 to 6.11 μg/ml).

The minimum plasma concentration observed during the rapid loading infusion was 1.20 μg/ml. At the end of the rapid loading infusion, plasma pirmenol concentration averaged 2.43 ± 0.65 μg/ml. Plasma pirmenol concentration during the maintenance infusion remained nearly constant for each subject and ranged from 0.94 μg/ml to 2.75 μg/ml (mean 1.66 ± 0.52 μg/ml) for all subjects and was close to the predicted concentration of 1.75 μg/ml. Four subjects who received a 4-hour infusion during double-blind testing and a more prolonged infusion during open-label testing had very comparable plasma concentrations during both infusions (Fig. 3). The intersubject variation in concentration was not related to differences in subject weight or body surface area.

Effect of pirmenol on blood pressure, heart rate, and electrocardiographic intervals: Table I is a comparison of measured variables during the infusion of pirmenol. Systolic blood pressure, heart rate, and P-R interval were not significantly influenced by pirmenol. There was a slight but statistically significant ($p = 0.03$) increase in diastolic blood pressure during 4-hour infusions. Analysis of the first 2 hours of the infusion separately from the last 2 hours of infusion revealed no progressive increase in diastolic blood pressure during the course of the infusion. Moreover, the increase was not maintained during infusions longer than 4 hours. No subject manifested a clinically important increase in blood pressure.

There were also slight increases in QRS duration and corrected Q-T interval during infusions of pirmenol. Again there was no apparent tendency for progressive prolongation during infusions.

Adverse effects: The 12 infusions in 8 subjects represented 142 hours of pirmenol administration. No subject had any symptoms or adverse effects during infusion. One subject had mild erythema at the infusion site that may have been related to 24 hours of pirmenol infusion.

No laboratory abnormalities or changes in renal, hepatic, or hematologic assessment were associated with pirmenol infusion.

Discussion

In this study, we used a randomized, double-blind, placebo-controlled design to establish that a continuous pirmenol infusion had sustained antiarrhythmic activity in patients with PVBs. Additionally, the infusion regimen produced stable plasma pirmenol levels for up to 48 hours. The antiarrhythmic effect was sustained throughout the longest infusions, indicating a lack of tachyphylaxis to the therapeutic effect of pirmenol. No clinically important toxicity was observed. This demonstration of sustained antiarrhythmic effect and the lack of toxicity suggests that intravenous pirmenol may be an alternative to lidocaine for treatment of ventricular arrhythmias.

Patients enrolled in our study were clinically stable; they did not have symptomatic ventricular tachycardia. However, we believe that these stable patients are an appropriate population for initial clinical testing of new drugs for the treatment of ventricular arrhythmias. Unstable patients with acute myocardial infarction or symptomatic ventricular tachycardia are likely to be less suitable for a carefully controlled clinical trial such as this one with a placebo phase.

Hammill et al[4,5] suggested that 1.0 μg/ml was the minimal therapeutic concentration of pirmenol based on the reappearance of arrhythmia after short-term infusions. A ≥90% reduction in PVBs was observed with plasma concentrations in the range of 0.7 to 2 μg/ml after oral[5] and 1 to 3.8 μg/ml after intravenous administration; no important toxicity was observed. In the present study, the 3-stage infusion regimen is seen to be very effective in rapidly achieving and maintaining stable plasma pirmenol levels from 0.9 to 2.75 μg/ml. Pirmenol did not accumulate during the infusion. The infusion regimen was designed for maximum simplicity. The first stage was a 50 mg bolus, which was delivered by a hand-held syringe. The second stage (2.5 mg/min for 1 hour) was exactly 10× the third stage (0.25 mg/min continued indefinitely). Our present study extends the safety of pirmenol at therapeutic levels for up to 48 hours. No symptoms were reported by any patient during infusion and no important changes were observed on physical examination or extensive laboratory profiles.

Diastolic blood pressure increased significantly during infusions, perhaps due to the suppression of PVBs and a consequent increase in effective heart rate. Two subjects had diastolic pressures >90 mm Hg (but <100 mm Hg), but the increase in diastolic pressure was neither progressive nor maintained during prolonged infusions. A recent hemodynamic study of pirmenol

TABLE I Effect of Pirmenol and Placebo Infusion on Blood Pressure, Sinus Rate, and Electrocardiographic Intervals

	Control	Placebo Infusion	Control	Pirmenol Infusion
Systolic blood pressure (mm Hg)	135 ± 18	137 ± 21	130 ± 16	136 ± 18
Diastolic blood pressure (mm Hg)	76 ± 7	76 ± 5	74 ± 6	86 ± 8*
Sinus rate (beats/min)	74 ± 13	72 ± 7	70 ± 10	73 ± 10

Data were obtained during double-blind infusions of pirmenol and of placebo ($n = 6$). Control data are the average of measurements during the 1-hour control period. Infusion data represent measurements obtained during the infusion period. The corrected Q-T interval was calculated as Q-T/$\sqrt{}$ R-R interval.

concluded that pirmenol was unlikely to cause important myocardial depression, at least in patients with normal left ventricular function.[8]

Pirmenol infusions prolong QRS duration and corrected Q-T interval approximately 10%. This has been observed in previous human studies[4,5] and is consistent with the local anesthetic action of pirmenol observed in isolated dog Purkinje fiber preparations.[1] Importantly, prolongation of the QRS duration and Q-Tc interval were not progressive during extended infusions.

In conclusion, the present study demonstrates that our 3-stage intravenous regimen satisfactorily achieved and maintained plasma pirmenol levels that suppressed PVBs with no toxicity. Pirmenol is a promising agent that warrants further evaluation in other types of arrhythmias.

Current Physiologic Pacemakers: A Serious Problem With a New Device

JOSEPH W. RUBIN, MD, CM, MARTIN J. FRANK, MD, JOHN P. BOINEAU, MD, and ROBERT G. ELLISON, MD

Twenty adults underwent implantation of an automatic (DDD) pacemaker (Medtronic model 7000, Versatrax I) for treatment of symptomatic bradyarrhythmias. Only 9 patients had optimal DDD mode pacing during 78 paced months. In 3 patients, the DDD mode was changed to atrioventricular (AV) sequential (DVI) early because of risk imposed by sustained tachycardia upon underlying myocardial ischemia. The remaining 8 had had tachycardia due to pacemaker reentry, and 7 had neurologic and cardiovascular symptoms. DDD pacing was abandoned in 5 when reentry could not be interrupted by digitalis administration or reprogramming. Three continue to be paced in DDD mode despite intermittent reentrant tachycardias, with digitalis diminishing episodes of reentry in only 1. Mean ventriculoatrial conduction time was 229 ± 34 ms. Reentrant pacemaker tachycardia developed in 7 of 12 with normal or nearly normal AV conduction, but in only 1 of 5 with complete heart block. Preimplantation electrophysiologic study did not reliably detect and initial postoperative Holter monitoring did not predict reentrant tachycardia. The risk of reentry caused by a short, fixed atrial refractory period combined with the high occurrence of slow retrograde AV conduction, particularly in patients with normal or nearly normal anterograde conduction, renders the Versatrax I and other similar pacemakers unsuitable for DDD mode pacing in many patients.

Properly timed atrial systole maintains reduced filling pressure, which facilitates venous return, augments ventricular filling, assists closure of atrioventricular (AV) valves, and thereby improves ventricular function. Typically, the increment in cardiac output achieved by preserving AV synchrony over a rate-matched, paced ventricular rhythm (lacking synchronous atrial systole) approaches 20%.[1–7]

Fully automatic pacemakers are indicated in AV block with normal sinus nodal function. Their use may be indicated in persons requiring atrial demand (AAI), P-synchronous (VDD), or AV sequential (DVI) pacing.[8] Because of the necessity for atrial-sensing and ventricular-triggering functions, the pacemaker can behave as the efferent limb of a reentrant tachycardia if retrograde atrial excitation initiated by ventricular pacing is sensed by the atrial electrode. The ensuing ventricular stimulus is premature and recurrent retrograde conduction causes a sustained tachycardia.

This report reviews early results in 20 patients who received fully automatic pacemakers for treatment of symptomatic bradyarrhythmias. The high frequency of reentrant tachycardias observed supports the importance of modification of currently available automatic pacemakers to minimize the threat of sustained, pacemaker-mediated tachycardia.

Methods

Twenty adults underwent implantation of a fully automatic pacemaker (Medtronic model 7000, Versatrax I) between December 1, 1981, and November 30, 1982. The Versatrax I is a multiprogrammable, lithium-powered, dual-chamber device which employs a unipolar electrode in atrium and ventricle. The hermetically sealed case serves as the indifferent electrode for both leads. Externally programmable features include mode (VVI, DVI, or DDD), AV interval, rates, rate limits, and independent adjustment of each electrode's pulse width and sensitivity. However, the atrial refractory period measured from the ventricular stimulus or a ventricular-sensed event is fixed at 155 ms.

Eight patients underwent preimplantation electrophysiologic studies to define sinus nodal and conduction system

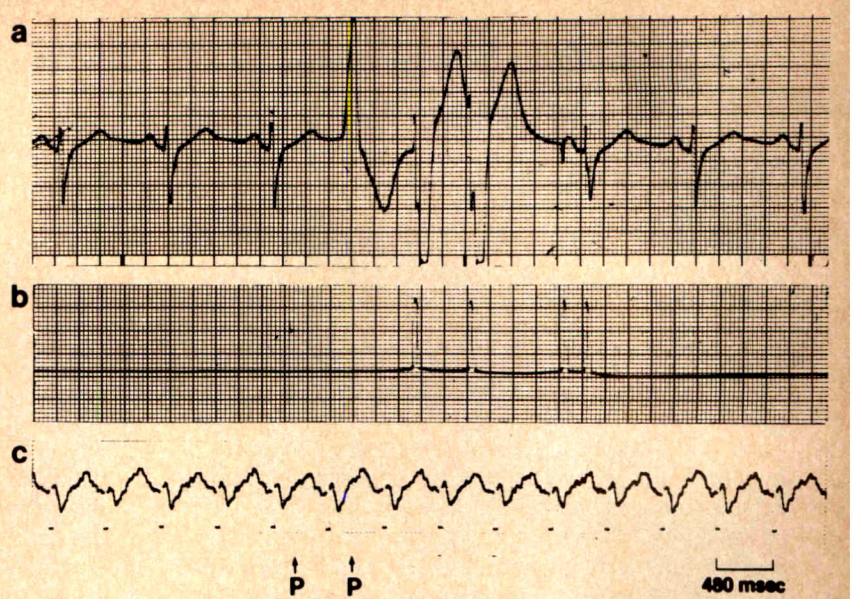

FIGURE 1. Fifty-two-year-old man (Group II) after pacemaker implantation (see text). **a,** early postimplantation Holter (first channel). Three normal sinus beats: ventricular premature beat followed by 2 paced ventricular beats at R-R interval of 480 ms (programmed upper rate limit). Patient recovers normal sinus rhythm spontaneously after single AV sequential (DVI) paced cycle. **b,** early postimplantation Holter timing trace (second channel). Single artifacts are ventricular stimuli in response to sensed reentrant "P"-waves at programmed upper rate limit. Paired artifacts of DVI cycle are atrial and ventricular separated by programmed AV delay of 200 ms. **c,** eight days after implantation telephone surveillance electrocardiogram which demonstrates sustained P-synchronous ventricular-paced tachycardia at 125 ppm (programmed upper rate limit). **P** marks retrograde P-wave approximately 200 ms after the ventricular artifact.

function. An attempt also was made to detect retrograde right ventricle-to-right atrium conduction by pacing from several sites in the right ventricle and recording from the right atrial appendage.

All 20 patients had a ventricular electrode (Medtronic model 6971) and an atrial electrode (Medtronic model 6991U) inserted under fluoroscopic control using standard implantation techniques. Electrode impedance of 300 to 700 ohms was ascertained. Filtered and unfiltered intracavitary electrograms were recorded from the electrodes to assure adequate voltage for the pacemaker-sensing amplifiers. Voltage threshold for capture was measured as a function of pulse duration in order to guarantee myocardial stimulation.

Ambulatory electrocardiographic (ECG) monitoring was employed in all patients for 18 to 39 hours after implantation to assure proper pacemaker function. A 2-channel pacemaker recording unit (Del Mar Avionics model 448), which recorded an ECG lead on 1 channel and the pacemaker stimulus artifacts on the other channel, was routinely used in interpreting electrical events (Fig. 1, a and b). Three atrial leads became dislodged and were successfully repositioned. All patients were discharged without surgical complications and were followed up in our telephone surveillance clinic. Inpatient and outpatient monitoring was conducted with particular attention to the identification of a supraventricular tachycardia in which the pacemaker programmed in DDD mode formed 1 limb of a reentrant loop. Such a loop would be closed by the atrial amplifier sensing recurrent ventriculoatrial (VA) conduction that occurs >155 ms from the ventricular event.

Reentry induced by a pacemaker functioning in DDD mode was defined as a regular sustained tachycardia at a rate equal to the programmed upper rate limit. The instantaneous cessation of this tachycardia, either by reprogramming the pacemaker to a lower rate without atrial sensing (VVI or DVI mode) or by applying a magnet over the pulse generator and converting to DVI mode temporarily, further identified the arrhythmia as pacemaker-induced. The ECG pattern of pacemaker-induced tachycardia is characterized by the pacemaker functioning normally in a P-synchronous manner with retrograde P-waves (sensed), followed by a paced ventricular beat triggered by the sensed atrial event at the preset upper rate limit. VA conduction times were measured from the ventricular artifact to the beginning of the retrograde P-wave. P-wave duration to point of sensing was not measured.

TABLE I Summary of Initial Clinical Experience in 20 Patients Receiving Versatrax I Pacemakers

Group	First Paced DDD (n)	With Retrograde Reentry (n)	Retrograde Times (ms)*	Now Paced DVI (n)
I	10	5	180, 220, 240, 260, 280	6
II	5	2	200, 200	2
III	5	1	250	0
Totals	20	8		8

* Mean retrograde conduction time 229 ± 34 ms.
Group I = sinus bradycardia with normal AV conduction; Group II = sinus rhythm with prolonged AV conduction; Group III = complete heart block.

Results

Table I summarizes our initial clinical experience. Indications for artificial cardiac pacing in all patients were symptomatic bradyarrhythmias characterized by sinus bradycardia with normal AV conduction in 10 (Group I), sinus rhythm with prolonged AV conduction in 5 (Group II), and complete heart block in 5 (Group III). In addition, of the 5 Group II patients, 4 had ≥1 syncopal episodes, 2 had hypertrophic cardiomyopathy, 1 had dilated cardiomyopathy, and 2 had abnormal sinus nodal function. All 20 patients have been followed from 2 to 12 months for a total of 78 months.

In Group I, 5 had pacemaker-mediated reentrant tachycardias. Retrograde conduction times ranged from 180 to 280 ms. Digitalis controlled reentrant tachycardia in 1 but not in another. Reduction of the upper rate limit eliminated the symptoms but not the reentrant tachycardia itself in a third. DDD mode was abandoned in 3 because both reprogramming and drug intervention failed to control symptomatic reentrant rhythms. DVI mode was selected early in 3 others because of the risk

imposed by reentrant tachycardias upon underlying ischemic heart disease. Of the 10 Group I patients, only 4 continued to have DDD mode pacing.

Two Group II patients suffered reentrant rhythms that could not be controlled by either reprogramming or drugs; DDD pacing was abandoned in these patients. Retrograde times were 200 ms in both instances (Fig. 1). All Group III patients have had successful DDD mode pacing. One, who is asymptomatic, has intermittent episodes of pacemaker-mediated reentrant tachycardia with a retrograde time of 250 ms. The mean retrograde conduction time in the 8 patients from Groups I, II, and III who manifested reentrant rhythms was 229 ± 34 ms.

Figure 1 illustrates an instance of pacemaker-initiated reentrant tachycardia in a 52-year-old man (Group II) who presented with a recent history of recurrent syncope. Hypertrophic cardiomyopathy was previously diagnosed and several 24-hour ECG recordings demonstrated frequent multifocal ventricular premature beats without coupling or runs of ectopic rhythm. An electrophysiologic study demonstrated an H-V interval of 115 ms. Programming extrastimuli at different coupling intervals in the right ventricle failed to elicit retrograde conduction. Although the frequency of ventricular premature beats was controlled with propranolol and disopyramide, syncope recurred. No ECG data were ever obtained during syncope. A Versatrax I pacemaker was implanted. Figure 1a, an excerpt of the early postimplantation Holter recording, illustrates 1 of several brief and self-limited episodes of pacemaker reentry at the programmed upper rate limit (125 pulses/min). The patient was discharged from the hospital with his previous drug regimen and the addition of digitalis to block the retrograde conduction. Eight days after implantation, the patient contacted the pacemaker surveillance clinic complaining of continuous palpitations, overwhelming weakness, and dizziness. The telephone surveillance electrocardiogram (Fig. 1c) revealed a sustained P-synchronous ventricular-paced tachycardia at the pacemaker's programmed upper rate limit. Reprogramming the pacemaker to DVI mode relieved the tachycardia and the patient's complaints. Digitalis was discontinued. After 6 months of observation, syncope has not recurred and the patient has returned to work.

Neither preimplantation electrophysiologic study nor postimplantation ambulatory ECG monitoring predicted the occurrence of pacemaker-mediated tachycardias. In 8 of the original 20 patients, attempts to elicit retrograde conduction during electrophysiologic study performed without sedation or parasympathetic blocking agents failed before pacemaker implantation. Nevertheless, reentrant supraventricular tachycardia with the pacemaker acting as 1 limb of the reentrant loop occurred in 2. Ambulatory ECG monitoring detected reentrant rhythms immediately in only 3, and from 3 days to 3 months after implantation in the remaining 5. Four of the 5 with late detection of reentry had no evidence of supraventricular tachycardia during ambulatory ECG recordings immediately after implantation.

Seven of the 8 patients with reentrant tachycardia had neurologic and cardiovascular symptoms at the time the arrhythmia was detected, including postural dizziness, peripheral weakness, and dyspnea at rest or with minimal exertion. Serious complications were 2 cases of pulmonary edema and 1 case of unstable angina pectoris due to unrelenting tachycardia. Reprogramming to slower rates in DVI mode partially relieved the symptoms and signs of the complications in all 3 cases.

Discussion

A pacing system which restores AV synchrony over a physiologic range of rates was described by Funke and Herpers in 1978.[9] The Versatrax I, which is a more advanced version of the Funke device, is described as a "fully automatic" (DDD or DD-T/I) atrial synchronous, atrial demand, ventricular demand device. This pacemaker can stimulate the atrium only in sinus bradycardia without block (AAI mode), atrium and ventricle sequentially in sinus bradycardia with block (DVI mode), or P-synchronously in block with normal sinus nodal function (VDD or VD-T/I mode). It can also remain in standby mode during normal sinus rhythm. Ventricular inhibition minimizes the chance of competitive ventricular rhythms. Operation shifts logically and automatically from 1 mode to another, on a beat-to-beat analysis of the underlying rhythm by the device's logic circuitry. A fixed atrial-sensing refractory period after a ventricular event of 155 ms was tacitly assumed to be an adequate time to filter out most rapidly conducted retrograde P-waves capable of initiating an undesirable, pacemaker-induced tachycardia. A prolonged atrial refractory period appeared to be undesirable because of limitations necessarily imposed upon the maximum atrial tracking rate of the pacemaker in response to a physiologic sinus tachycardia.[10,11]

In 1981, Morley et al[10] emphasized the importance of recognizing retrograde AV conduction in patients selected for physiologic pacing systems. Of their patients with persistent or intermittent high-grade block, 32% had retrograde conduction during electrophysiologic study. Of those with no evidence of AV conduction abnormality, 90% had retrograde P waves. Mean retrograde time was 206 ± 42 ms with a range of 160 to 330 ms, a retrograde time very similar to the 229 ± 34 ms of our study. This study warned of the possibility of reciprocating tachycardias in pacing systems with short atrial refractory periods. Our results corroborate Morley's findings. We have found that pacemaker-induced supraventricular tachycardia is a common problem among patients without complete heart block but is infrequent in the patients with complete anterograde AV block (Table I).

Our clinical experience reveals that we cannot rely upon detection of retrograde conduction during electrophysiologic study or the absence of reciprocating rhythms on routine, early postimplantation ambulatory ECG recording to prevent real or potential clinical complications. Moreover, we cannot eliminate the possibility of triggering reentry after retrograde con-

duction caused by random ventricular ectopic beats.[11–13] During our more recent experience, the pacemakers of 3 patients were intentionally programmed to DVI mode because of potential risk imposed by a pacemaker-induced tachycardia upon underlying ischemic heart disease.

Several reports have cited cases of complex rhythm disorders associated with pacemakers capable of synchronizing ventricular systole with atrial activation.[14–16] Other data from electrophysiologic studies in man illustrate >90% incidence of retrograde conduction as a result of ventricular extrasystoles. Retrograde conduction times >390 ms were common. Shorter VA conduction times were only infrequently associated with reciprocal rhythms, whereas longer times frequently induced the reentry mechanisms.[12] Our clinical data illustrate retrograde conduction times (229 ± 34 ms) within the range often associated with reentrant tachycardias.

The occurrence of 3 potentially fatal complications due to pacemaker-induced tachycardia suggests that we should carefully observe Morley's warning[10] and eliminate the possibility of slow retrograde conduction before programming the Versatrax I to operate in DDD mode. Ideally, the investigation for retrogrades could be performed at the time of atrial and ventricular electrode insertion. Because of our lack of success in demonstrating retrograde conduction, we have debated the value of pursuing any electrophysiologic study before using the Versatrax I. We should have anticipated the high incidence of retrograde conduction in Group I. These patients with normal anterograde conduction would have responded well to atrial demand pacing (AAI). Establishing a pulse generator AV delay well in excess of their normal AV conduction times should have effectively caused the Versatrax I to function automatically in AAI mode in these patients. The expected result was not achieved in any Group I patient who had reentry. Some of our records suggest that retrograde conduction followed a random ventricular extrasystole which then entrained the sustained P-synchronous pacemaker response at the programmed upper rate limit (Fig. 1a).

We must conclude that a pulse generator atrial refractory period of 155 ms renders the Versatrax I very vulnerable to potentially dangerous reciprocating tachycardias. Such a device is unsatisfactory for DDD pacing in many patients, particularly those with sinus bradycardia and normal or nearly normal AV conduction. Among the theoretical pulse generator-based algorithms for recognizing and managing sustained pacemaker reentry, we believe that prolonging the atrial refractory period to encompass the expected mean retrograde conduction time is the least complex and potentially most effective choice. While a longer refractory period imposes an upper limit upon the maximum physiologic atrial rate which would guarantee 1-to-1 atrial synchronous, ventricular pacing, the threat of reciprocating rhythms due to slow retrograde conduction will be significantly reduced or eliminated. The implied decrease in maximum atrial tracking rate would not seriously compromise the daily routine of the majority of our patients who might otherwise benefit significantly from DDD mode pacing. The often intermittent nature of slow reentry renders electrophysiologic study before implantation and ambulatory ECG after implantation unreliable as predictors of this most serious complication of physiologic pacing systems. External programming control of the atrial refractory period may obviate the need for pursuing a diagnosis of retrograde conduction before implantation. A controllable atrial refractory period will allow more liberal use of physiologic pacing systems in the treatment of symptomatic bradyarrhythmias.

Left Ventricular Function at Rest and During Exercise in Congenital Complete Heart Block: A Radionuclide Angiographic Evaluation

BRUNO V. MANNO, MD, A-HAMID HAKKI, MD, ESHAGH ESHAGHPOUR, MD, and ABDULMASSIH S. ISKANDRIAN, MD

This study evaluates intrinsic cardiac performance during upright exercise in patients with congenital complete heart block. Left ventricular ejection fraction and volume were measured at rest and peak upright exercise with radionuclide angiography in 5 patients aged 11 to 39 years with congenital complete heart block: 4 were in New York Heart Association class I and 1 was in class II. The resting cardiac output was maintained at a normal level by an increase in end-diastolic volume rather than by a decrease in end-systolic volume. The left ventricular ejection fraction was normal at rest in all patients, but an abnormal response to exercise was noted in 3 patients. There was no appreciable change in the end-diastolic volume during exercise. Thus, patients with congenital complete heart block utilize the Starling mechanism to maintain normal resting cardiac output, but the response to exercise is usually abnormal even in the absence of symptoms.

Congenital complete heart block (CHB) is uncommon, occurring in 1:5,000 to 1:20,000 live births.[1,2] Several previous studies[3–7] have described the exercise tolerance and changes in heart rate, cardiac output, and blood pressure during exercise in a few patients, but changes in ventricular volume and function have not been described. Herein we report left ventricular (LV) ejection fraction (EF) and volume at rest and during upright exercise in 5 patients with congenital CHB.

Methods

Five patients with congenital CHB, 4 female and 1 male between the ages of 11 and 39 years, were studied (Table I). Criteria[1,8] for diagnosis of congenital CHB included (1) CHB noted before birth or during infancy; (2) independence of atrial and ventricular rates; (3) ventricular rate slower than atrial rate; and (4) absence of history of other factors that may cause CHB after birth.

The electrocardiograms revealed QRS complexes of normal duration in 4 patients and prolonged QRS duration in 1 patient (Case 5). One patient (Case 4) had a maternal history of systemic lupus erythematosus,[9] and also trivial aortic regurgitation. The remaining 4 patients had no associated cardiac abnormalities. No patient was receiving cardioactive medication; 4 patients were in New York Heart Association functional class I and 1 patient (Case 4) was in class II. No patient had electrocardiographic criteria for LV hypertrophy. A systolic ejection murmur (left sternal border and grade 1/6) was heard in 4 patients (Cases 2 to 5).

Exercise testing: Exercise studies were performed with the patient in the upright position, using a variable-load bicycle ergometer (Quinton Instruments). The method of exercise testing has been described.[10] The exercise endpoints were dyspnea (Patients 1 and 3); fatigue (Patients 2 and 4) and dizziness (Patient 5). First-pass radionuclide angiograms were obtained at rest and peak exercise by means of a computerized multicrystal gamma camera (Baird-Atomic System-77). The LVEF, end-diastolic volume, and end-systolic volume were measured according to a previously described method from this laboratory.[10,11] All volumes were subsequently indexed by dividing the measurement by the body surface area in square meters.

Results

The cardiac index at rest was normal in 4 patients. The patient with reduced cardiac index (Patient 5) had the smallest end-diastolic volume (Table I). All 5 patients had normal EF but increased end-diastolic volume indexes at rest (limits of normal values in our laboratory are $\geq 50\%$ and < 100 ml/m^2, respectively). Thus,

AR = atrial rate (beats/min); BP = blood pressure (mm Hg); CI = cardiac index (liters/min/m^2); EF = ejection fraction (%); EDVI = end-diastolic volume index (ml/m^2); ESVI = end-systolic volume index (ml/m^2); Ex = exercise; R = resting; SVI = stroke volume index (ml/m^2); VR = ventricular rate (beats/min).

the resting cardiac output is maintained normal by an increase in end-diastolic volume rather than a decrease in the end-systolic volume. During exercise, the cardiac index increased in all patients. The smallest change was observed in the oldest patient in the group (Patient 3). Only 1 patient was able to double the cardiac output. The EF increased by at least 5% (absolute units and normal response) in 2 patients (Cases 2 and 5), remained unchanged (<5% change) in 2 patients (Cases 1 and 4), and decreased in 1 patient (Case 3). The patient with a decrease in EF during exercise was the oldest patient in the group. The 2 patients with normal EF responses to exercise had greater exercise tolerance than the remaining patients. These 2 patients had a decrease in end-systolic volume during exercise, but the remaining 3 patients had an increase. There was no appreciable change in the end-diastolic volume with exercise in all 5 patients.

Discussion

There are few studies describing hemodynamic abnormalities during exercise in patients with congenital CHB. These studies, in a total of 8 patients, described the changes in cardiac output, heart rate, and stroke volume. Studies in larger numbers of patients have been reported describing the changes in atrial and ventricular rates.[3–7,12–15]

Our results showed that the cardiac output increased during exercise in patients with congenital CHB, and that this increase was due to an increase in ventricular rate. Although the cardiac output increased in all 5 patients with exercise, only 1 patient was able to double the cardiac output. The resting cardiac output was maintained in these patients, despite the slow ventricular rate, by LV dilation. This finding is in agreement with other clinical and experimental studies in which the cardiac volume was measured with roentgenography.[3,16] One of the 5 patients (Case 5) had reduced cardiac output at rest; this patient also had the smallest end-diastolic volume index. No patient had an increase in end-diastolic volume during exercise. The LVEF at rest was normal in all 5 patients; however, an abnormal response to exercise was observed in 3 patients. The worst LV function during exercise was observed in the oldest patient in the group (Patient 3), and this was the only patient who was in functional class II; this patient had no historic evidence or risk factors to suggest the presence of associated coronary heart disease. The remaining patients were asymptomatic.

The reason(s) for abnormal cardiac reserve function during exercise in some patients with congenital CHB is not clear but may be attributable to chronic volume overload, similar to that observed in patients with chronic aortic regurgitation,[10,17–19] and this abnormality may be more pronounced in the older patient.[17] In this and other studies,[3–5] the exercise capacity was not related to the cardiac output. Taylor and Godfrey[4] suggested increased peripheral extraction of oxygen and the ability to tolerate low venous oxygen tensions as possible mechanisms to maintain a normal working capacity in such patients.

The contribution of atrial activity to ventricular filling and cardiac output is not clear from our study. The patient with the lowest atrial rate at rest and exercise had the lowest cardiac output at rest and exercise. However, this patient (Case 5) also had the smallest end-diastolic volume.

The hemodynamic responses to exercise in patients with congenital CHB are therefore entirely different from those observed in normal subjects, who increase their cardiac output during upright exercise by increases in heart rate and stroke volume and who also have increases in EF, a slight increase in end-diastolic volume, and a decrease in end-systolic volume.[10,20,21]

Idiopathic Paroxysmal Ventricular Tachycardia With a QRS Pattern of Right Bundle Branch Block and Left Axis Deviation: A Unique Clinical Entity With Specific Properties

FUN-CHUNG LIN, MD, C. DAVID FINLEY, MD, SHAHBUDIN H. RAHIMTOOLA, MD, and DELON WU, MD

Electrophysiologic evaluation before and after the serial administration of verapamil, lidocaine, propranolol, and procainamide was undertaken in 4 young, asymptomatic patients with recurrent, sustained ventricular tachycardia (VT). No patient had obvious organic heart disease. The electrocardiogram during sinus rhythm showed S-T depression and T-wave inversion over the inferior and lateral precordial leads in 3 patients. QRS morphologic characteristics during episodes of VT showed a pattern of right bundle branch block and left axis deviation. In all 4 patients, VT could be both induced and terminated with electrical stimulation. Verapamil terminated VT and prevented the induction o sustained VT in 3 patients, and markedly slowed the rate of VT in 1 patient. Procainamide effectively prevented the induction of sustained VT in 2 patients and although ineffective in preventing induction ir 2 patients, it slowed the rate of tachycardia in both. Lidocaine and propranolol did not prevent the induction of VT in any patient. These findings suggest that slow-response tissues may be involved in the genesis of VT in these patients, and that VT in these patients may represent a unique clinical entity with distinct electrocardiographic, electrophysiologic, and electropharmacologic properties.

Sustained ventricular tachycardia (VT) usually occurs in patients with organic heart disease, particularly in patients with a myocardial aneurysm subsequent to myocardial infarction.[1–4] Reentry is the most common mechanism of VT in these patients.[1,5] Nonetheless, sustained VT may occur in patients without demonstrable organic heart disease,[1,2,6,7] and mechanisms other than reentry may be responsible for VT in some.[6,7] In this study, we report on 4 young, asymptomatic patients with recurrent, sustained VT but without obvious organic heart disease. Their electrocardiographic manifestations of VT, electrophysiologic behavior, and pharmacologic responses were unique.

Methods

This study consisted of 4 young, asymptomatic patients, 2 female and 2 male, aged between 24 and 35 years (mean 27), with electrocardiographic documentation of recurrent, sustained VT manifesting a QRS pattern of right bundle branch block (BBB) and left axis deviation (LAD). In 3 patients the spontaneous episodes of VT could be terminated by intravenous administration of 5 to 10 mg of verapamil during emergency room visits.

All electrophysiologic studies were performed in the postabsorptive, nonsedated, and supine state after having obtained written informed consent. A #6 quadripolar electrocatheter was percutaneously introduced into the right femoral vein, advanced to the right atrium, and positioned across the tricuspid valve. The distal 2 electrodes were used for right ventricular stimulation, whereas the proximal 2 electrodes were used for His bundle recording. A #7 hexapolar electrocatheter was introduced into a right antecubital vein through a small incision and advanced to the right atrium and then into the right ventricle. The distal 2 electrodes were used for right ventricular pacing, the middle 2 electrodes for recording of the right atrial electrogram, and the proximal 2 electrodes for right atrial stimulation. Surface electrocardiographic leads and intracardiac electrograms were simultaneously recorded on a multichannel oscilloscopic photographic recorder (Electronics for Medicine VR-16, White Plains, New York) at a paper speed of 100 mm/s. Electrical stimuli of 2 ms duration approximately twice the diastolic threshold were provided by a programmable digital stimulator (DTU PG 100, manufactured by Bloom and Associates, Narberth, Pennsylvania).

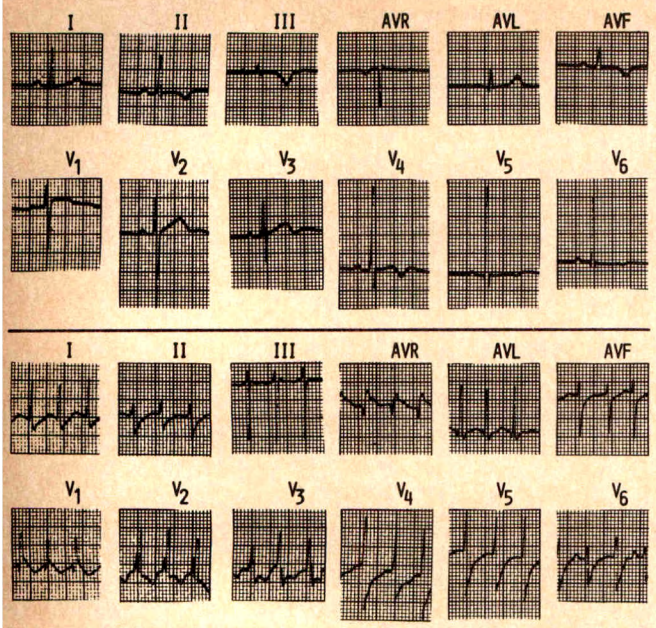

FIGURE 1. Electrocardiograms in case 1 showing ST-T changes over leads II, III, aVF, and V_4 through V_6 during sinus rhythm (**upper panel**) and a QRS pattern of right BBB and LAD occurring during a spontaneous episode of tachycardia (**lower panel**).

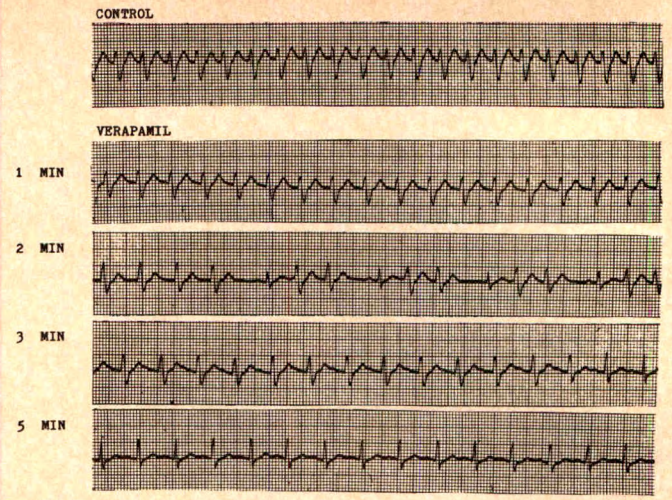

FIGURE 2. Rhythm strips of the monitor lead in case 3 showing termination of a spontaneous episode of VT after a bolus of 5 mg of verapamil. The rate of VT was 190 beats/min before verapamil (**first panel**) and slowed to a rate of 150 beats/min within 1 minute after the administration of verapamil (**second panel**). Intermittent sinus capture was noted within 2 minutes (**third panel**), whereas sinus capture with decreasing degree of fusion occurred within 3 minutes (**fourth panel**). Sinus rhythm was resumed within 5 minutes after verapamil (**fifth panel**).

Anterograde and retrograde conduction properties were evaluated by atrial and ventricular incremental pacing and extrastimulus testing techniques. Incremental atrial pacing was performed to the paced cycle length that induced second-degree block proximal to the His bundle recording site. Atrial extrastimulus with single or double premature stimulations was coupled to the sinus cycle length and an atrial driven cycle length. Incremental ventricular pacing was performed up to a paced cycle length of either 250 or 230 ms. Ventricular extrastimulus testing with single or double premature stimulations was coupled to the sinus cycle length and a ventricular driven cycle length.

After the control study, sustained VT was induced. An intravenous bolus of 5 mg of verapamil was given under continuous electrocardiographic monitoring. Regardless of whether or not termination of VT occurred, a second bolus of 5 mg of verapamil was given 5 minutes later. If spontaneous termination of VT was noted, the electrophysiologic study was repeated. Otherwise, an additional bolus of 5 mg of verapamil was repeated every 5 minutes either until VT was terminated or a total dose of 20 mg of verapamil had been administered, at which time VT was terminated with electrical stimulation and the study repeated. After this initial evaluation, the quadripolar catheter was removed and the tip of the hexapolar catheter was positioned at the right ventricular apex and secured for serial subsequent studies. On day 2, sustained VT was induced and 2 boluses of lidocaine (1 mg/kg) were administered with a time interval between doses of 5 minutes. If VT failed to terminate spontaneously within 10 minutes after the second bolus, it was terminated with electrical stimulation and the study repeated. On day 3, sustained VT was induced and intravenous propranolol (0.1 mg/kg) was administered. If VT did not terminate within 15 minutes of the dosage administration, it was terminated with electrical stimulation and the study repeated. On day 4, the patients were treated with oral procainamide 750 to 1,000 mg every 4 hours and the study repeated 2 hours after the sixth dose.

Conduction intervals and refractory periods are defined and measured as previously described.[8] The diagnosis of the VT was confirmed during electrophysiologic study by the demonstration of complete and incomplete atrioventricular dissociation, the occurrence of capture and fusion beats, and the demonstration of no His bundle potential preceding each QRS complex during the tachycardia. Reentry using a nodoventricular connection or a fasciculoventricular connection was excluded.[9]

Results

Clinical characteristics (Fig. 1 and 2): All 4 patients presented with a history of palpitations ranging from 3 to 12 years with episodes lasting from 10 minutes to 3 days. The frequency of attacks ranged from 3 per 12 years to 8 per year. No patient had obvious heart disease on physical examination, chest X-ray, echocardiogram, cardiac catheterization, and coronary angiography. In 3 patients multiple electrocardiograms taken during sinus rhythm showed S-T depression and T-wave inversion over leads II, III, and aVF, and in the lateral precordial leads (Fig. 1, upper panel). The electrocardiogram was normal in 1 patient (case 3).

The electrocardiograms recorded during spontaneous episodes of VT showed a QRS pattern of right BBB and LAD in all 4 patients (Fig. 1, lower panel). The QRS duration was 0.10 second in 2 patients and 0.12 second in 2 patients. The frontal QRS axis was between −60° and −100°. The rate of tachycardia ranged from 150 to 200 beats/min. Alternation of the cycle length of the VT was observed in 1 patient (case 1). In 3 patients VT was always terminated within a few minutes after the intravenous administration of 5 to 10 mg of verapamil (Fig. 2), whereas 1 patient (case 1) required cardioversion. In no patient was VT provoked by maximal treadmill exercise.

Induction of tachycardia (Table I and Fig. 3 to 5): Sustained VT identical to spontaneous VT was inducible with electrical stimulation in all patients. During induced VT, complete atrioventricular dissociation was

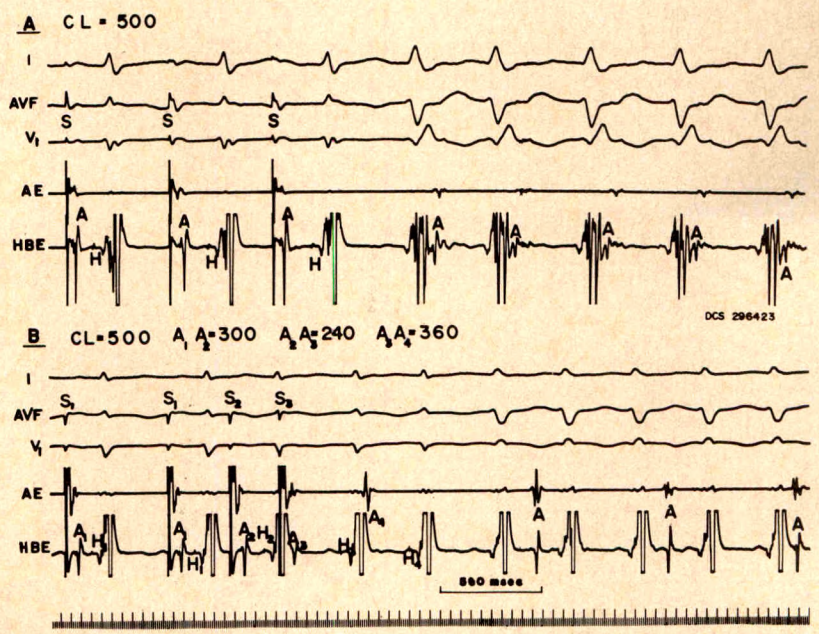

FIGURE 3. Recordings showing the induction of ventricular tachycardia (VT) with rapid atrial pacing in case 4 (**panel A**) and with double atrial premature stimulation in case 2 (**panel B**). In case 4 the VT was induced at an atrial paced cycle length of 500 ms, whereas in case 2 it was induced with 2 atrial premature stimulations at an atrial driven cycle length of 500 ms. The first coupling interval (A_1A_2) was 300 ms and the second coupling interval (A_2A_3) was 240 ms; A_3 induced a premature atrial beat (A_4) which was then followed by the initiation of VT. Note that the initiation of VT in both cases was independent of the development of right bundle branch block or left axis deviation, or both. During VT, intact ventriculoatrial conduction was noted in case 4 and complete atrioventricular dissociation was noted in case 2. A = atrial response to pacing stimulus; A_1 = atrial response to S_1; A_2 = atrial response to S_2; A_3 = atrial response to S_3; A_4 = premature atrial beat after A_3; AE = atrial electrogram recorded from right atrium; CL = cycle length; H = His bundle response to pacing stimulus; HBE = His bundle electrogram; H_1 = His bundle response to S_1; H_2 = His bundle response to S_2; H_3 = His bundle response to S_3; H_4 = His bundle response to A_4; S = pacing stimulus; S_1 = basic driven stimulus; S_2 = first extrastimulus; S_3 = second extrastimulus.

noted in 3 patients (cases 1 to 3) and intact ventriculoatrial conduction in 1 (case 4). Both capture and fusion beats were observed with appropriate atrial pacing. The QRS complex was not preceded by a His bundle spike. These findings are consistent with a diagnosis of VT. Sustained VT was inducible with incremental atrial pacing in 1 patient (case 4) (Fig. 3A), double atrial extrastimulus testing in 1 patient (case 2) (Fig. 3B), incremental ventricular pacing in all 4 patients (Fig. 4), and a single or double ventricular extrastimulus in 2 patients (cases 2 and 3). In 2 patients (cases 1 and 4), ventricular extrastimulus induced only 1 or 2 ventricular premature complexes with a QRS morphology similar to that of VT. In the 2 patients with atrial induction of VT, the induction was independent of the development of right BBB or LAD, or both, suggesting that macroreentry involving the bundle branches or fascicles is not likely to be the mechanism of VT (Fig. 3).[10] In 3 patients, the interval between the last ventricular paced beat and the initiating beat of VT or the interval between the ventricular extrastimulus and the initiating beat of VT was inversely related to the ventricular driven cycle length or the coupling interval of the extrastimulus (Fig. 4). In the remaining patient (case 3), no specific relation was found. The cycle length of VT ranged from 320 to 390 ms; alternation of the cycle length was observed in 1 patient (case 1) (Fig. 5A). In all 4 patients VT could be terminated with ventricular premature stimulation or a short burst of rapid ventricular pacing, or both.

Pharmacologic responses (Table I and Fig. 2, 5, and 6): Intravenous verapamil slowed the rate of VT in

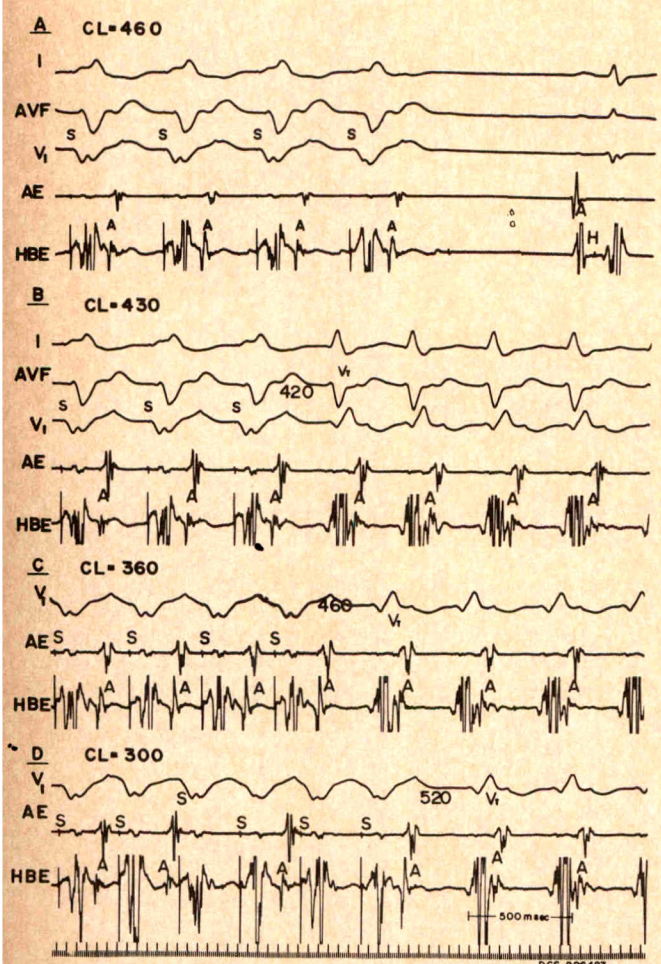

FIGURE 4. Recordings in case 4 showing an inverse relation between the ventricular paced cycle length (CL) and the interval of the last paced beat to the first beat of the VT (S-V_t interval). At a paced cycle length of 460 ms, VT was not induced (**panel A**); at a paced cycle length of 430 ms, VT was induced and S-V_t was 420 ms (**panel B**); at a paced cycle length of 360 ms, VT was induced and S-V_t was 460 ms (**panel C**); at a paced cycle length of 300 ms, VT was induced and S-V_t was 520 ms. V_t = first beat of the induced VT.

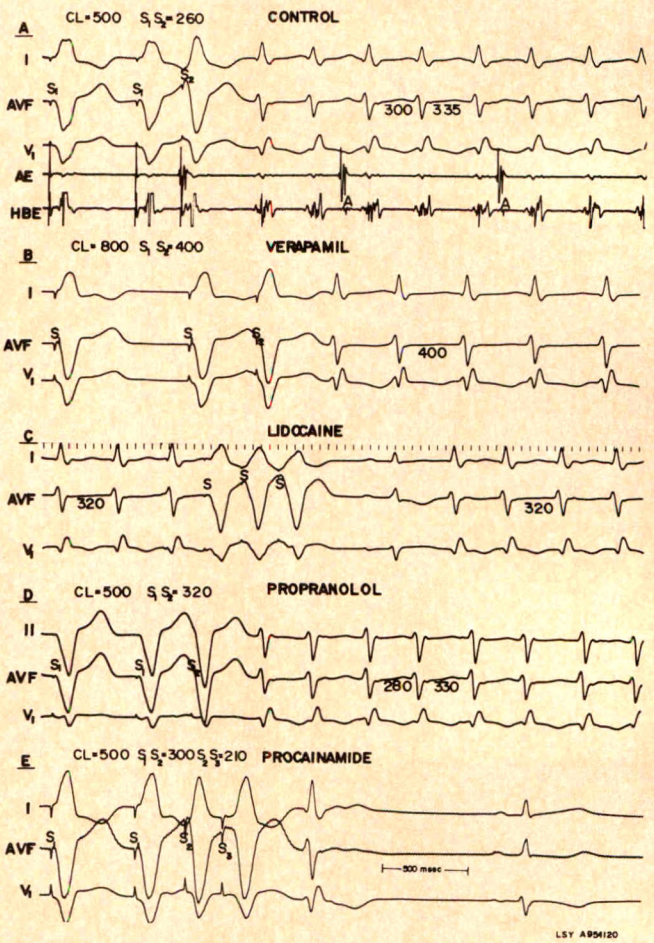

FIGURE 5. Recordings in case 1 showing the effects of verapamil, lidocaine, propranolol, and procainamide on induction of VT. Before drugs, sustained VT was induced during a ventricular paced cycle length of 500 ms at a ventricular coupling interval of 260 ms. Note an alternation of cycle length between 300 and 335 ms occurred during VT (**panel A**). With verapamil, sustained VT was induced during a paced cycle length of 800 ms at a coupling interval of 400 ms. The cycle length of VT lengthened to 400 ms (**panel B**). With lidocaine, the VT could not be terminated with a burst of rapid ventricular pacing which was followed by a sinus captured beat with resumption of the VT at a cycle length of 320 ms (**panel C**). With propranolol, sustained VT was induced during a paced cycle length of 500 ms at a coupling interval of 320 ms. The cycle length of VT again showed an alternation between 280 and 330 ms (**panel D**). With procainamide, only 1 premature ventricular complex with a QRS morphology being similar to that of VT was induced with double premature stimulations coupled to a basic paced cycle length of 500 ms. The first coupling interval was 300 ms and the second 210 ms (**panel E**).

all 4 patients and terminated VT in 3 of them (cases 2, 3, and 4). In 2 of these 3 patients, repeat electrophysiologic study showed an induction of either nonsustained VT (case 2) or 1 to 2 premature ventricular complexes of a QRS morphology identical to that of the VT (case 3) (Fig. 6B). In 1 patient (case 4), neither VT nor premature ventricular complexes were induced, but spontaneous ventricular complexes of a QRS morphology identical to that of the VT was observed after verapamil. The VT of the 1 patient which did not terminate after verapamil (case 1) was terminated with electrical stimulation. Repeat electrophysiologic study in this patient showed an induction of sustained VT (Fig. 5B). Of the 3 patients with induction of either VT or premature ventricular complexes, the induction occurred either at a longer ventricular paced cycle length or at a longer ventricular coupling interval as compared with that in the control study.

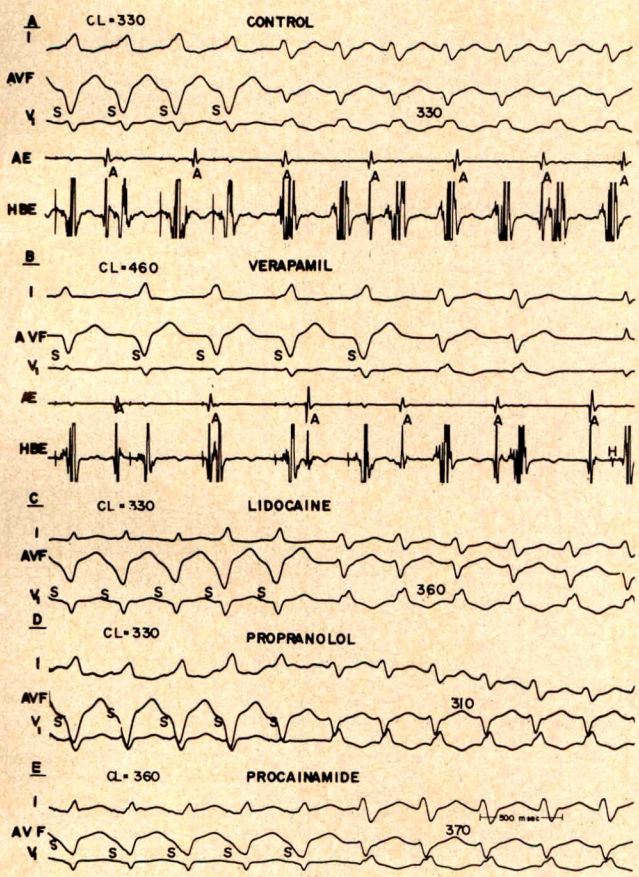

FIGURE 6. Recordings in case 3 showing the effects of verapamil, lidocaine, propranolol, and procainamide on induction of VT. VT was induced with rapid ventricular pacing. Before drugs, sustained tachycardia was induced at a paced cycle length (CL) of 330 ms. The cycle length of VT was 330 ms (**panel A**). With verapamil, 2 premature ventricular complexes with a QRS morphology identical to that of VT were induced at a paced cycle length of 460 ms (**panel B**). With lidocaine, sustained VT was induced at a paced cycle length of 330 ms. The cycle length of VT was 360 ms (**panel C**). With propranolol, sustained VT was induced at a paced cycle length of 330 ms. The cycle length of VT was 310 ms (**panel D**). With procainamide, sustained VT was induced at a paced cycle length of 360 ms. The cycle length of VT was 370 ms **(panel E).**

Intravenous lidocaine did not affect VT in 3 patients. In 1 patient (case 4), lidocaine terminated VT, but nonsustained VT continued to erupt during sinus rhythm. In 2 of the 3 former patients (cases 2 and 3), VT was converted to sinus rhythm with electrical stimulation. In 1 patient (case 1) VT could not be converted to sinus rhythm with electrical stimulation until a bolus of 5 mg of intravenous verapamil was administered (Fig. 5C). Repeat electrophysiologic study in these 3 patients showed induction of sustained VT (Fig. 6C).

Intravenous propranolol did not affect VT in 3 patients, and slowed the rate of VT in 1 patient (case 4). In the latter patient, VT terminated spontaneously, but was followed by repeated eruptions of nonsustained VT. In the former 3 patients, VT was terminated with electrical stimulation and repeat electrophysiologic study showed induction of sustained VT (Fig. 5D and 6D).

With oral procainamide, sustained VT could be induced in 1 patient (case 3) (Fig. 6E); 1 or 2 premature complexes of a QRS morphology identical to that of VT occurred in 1 patient (case 1) (Fig. 5E); and neither VT nor premature ventricular complexes could be induced in 1 patient (case 2). In the remaining patient (case 4), repeated eruptions of nonsustained VT were noted after procainamide administration. The cycle length of VT was longer after procainamide (Fig. 6A and 6E). Of the 2 patients with either induction of VT or premature ventricular complexes after procainamide (cases 1 and 2), induction occurred at either a longer ventricular paced cycle length or at a longer ventricular coupling interval as compared with that of the control study. The serum procainamide concentration was, respectively, 5.5, 6.9, 6.5, and 9.3 μg/ml in the 4 patients.

Discussion

The VT described in this study was unique in that (1) it occurred in young, asymptomatic patients without obvious organic heart disease; (2) the electrocardiogram during sinus rhythm showed a repolarization abnormality over the inferior and lateral precordial leads; (3) the QRS complex during the episodes of VT showed a pattern of right BBB and LAD; (4) the VT was inducible with ventricular stimulation and also with atrial stimulation on occasion; and (5) it responded to verapamil. These findings are similar to those in a recent study by Zipes et al[6] in 3 patients and Belhassen et al[14] in 1. All these patients had no demonstrable organic heart disease and all showed a QRS morphology of right BBB and LAD during VT. Treadmill exercise provoked VT in 1 patient.[6] In this study we further observed that a repolarization abnormality was frequently present in these patients and that VT was responsive to verapamil, partially responsive to procainamide, and nonresponsive to both lidocaine and propranolol. We suggested that VT in this group of patients represents a distinct clinical entity with unique electrocardiographic, electrophysiologic, and electropharmacologic properties.

Although reentry is the mechanism of sustained VT in patients with previous myocardial infarction or with other organic heart disease, the distinction between

reentry and triggered automaticity may not be possible using the catheter stimulatory and recording techniques.[12] Reentrant VT is characterized by (1) induction and termination of VT with appropriate electrical stimulation[1,4,6]; (2) demonstration of an inverse relation between the ventricular paced cycle length and the interval of the last ventricular paced beat to the initiating beat of VT or between the ventricular coupling interval and the interval of the ventricular coupled beat to the initiating beat of VT[1,6,12]; (3) demonstration of delayed conduction with a fragmented electrogram at the site of the reentrant circuit[5]; and (4) the responsiveness to procainamide and quinidine, but rarely to verapamil or propranolol.[13,14] The occurrence of alternation in cycle length during tachycardia is also suggestive of reentry, as it is seen frequently in patients with atrioventricular or atrioventricular nodal reentrant tachycardia.[15] VT due to triggered automaticity can also be initiated and stopped by premature stimulation or rapid pacing.[12] In 1 patient reported on by Zipes et al,[6] the number of induced premature ventricular complexes was related to the coupling interval of the premature beat, to whether 1 or 2 premature beats were introduced, and to the cycle length of the basic driven beats. They suggested that triggered automaticity could be the mechanism in this patient, as the amplitude of the triggered after-depolarization increases with the shortening of the driven cycle length or the coupling interval of the premature stimulation. Nevertheless, we believe that this phenomenon cannot absolutely exclude the possibility of reentry. Sustained reentry depends on a revolution time of longer duration than the effective refractory period of the reentrant circuit. Because the effective refractory period of the His-Purkinje and ventricular system shortens with shortening of the cycle length, induction of sustained VT is likely to occur at a shorter basic driven cycle length or a shorter coupling interval. In addition, a reflex increment of the sympathetic tone at a shorter driven cycle length or coupling interval may result in shortening of the effective refractory period and thus may facilitate induction of sustained tachycardia.

Likewise, the antiarrhythmic responses of VT do not suggest a specific mechanism. Procainamide, quinidine, lidocaine, and propranolol may affect reentrant VT by changing both the effective refractory period and the conduction time of the circuit. They may affect the VT due to triggered automaticity by decreasing the amplitude of the after-depolarization.[16–18] The fact that verapamil exerted a striking effect on the VT in our patients, nevertheless, suggests that slow-response tissue was involved in the genesis of VT.[16–18] Although reentry was likely to be the mechanism of VT in our patients, the possibility of triggered automaticity cannot be excluded absolutely.

A transient repolarization abnormality has been observed in patients with intermittent left BBB, with intermittent ventricular preexcitation, and after termination of both ventricular pacing and ventricular tachycardia.[19,20] The repolarization abnormality in our patients was observed over a prolonged period and thus did not appear to reflect a transient repolarization abnormality secondary to termination of VT.

In conclusion, we have described a distinct entity of recurrent, sustained VT occurring in young, asymptomatic patients without obvious heart disease. In these patients, the electrocardiogram taken during sinus rhythm frequently shows a repolarization abnormality over the inferior and lateral precordial leads. The VT is associated with a QRS morphology of right BBB and LAD and is inducible with atrial or ventricular stimulation, or both. Our study suggests that verapamil is highly effective and procainamide is partially effective, whereas lidocaine and propranolol are generally ineffective in the treatment of this arrhythmia.

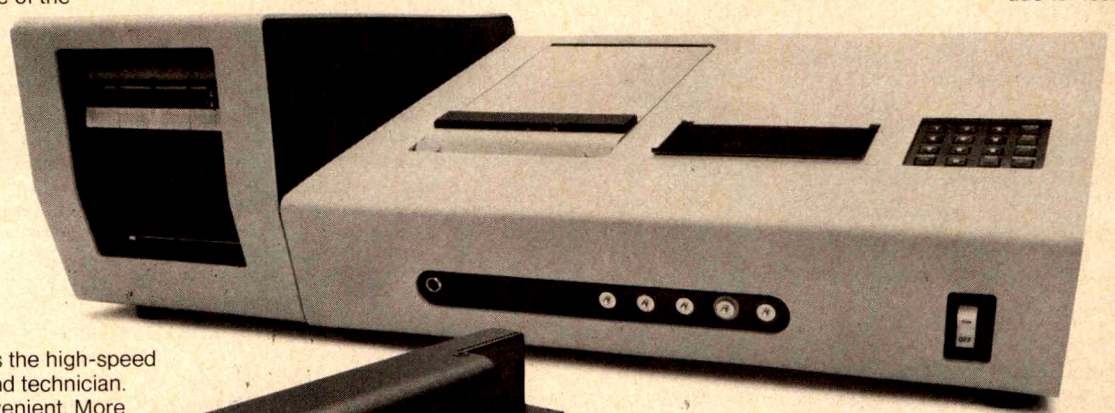
Clinical evaluation of various systems for analysis of ambulatory ECG records has been difficult to implement due to the variety of approaches to recording data, the operator-dependence of traditional recording and interpretation systems, and the subjective clinical judgements necessary in using the final results. One manufacturer can now report data utilizing a real-time approach to ambulatory monitoring that compares clinical accuracy to hand-counted data as a standard.[1]

In Holter studies, AEGIS™ gives you results in minutes... right in your office... without a specially trained operator.

• Provides the same clinical information as a scanning service—with none of the drawbacks.

• Fits easily into any office.

• System validates itself- no need for repeat studie due to "lost" data or faul equipmen



• Replaces the high-speed scanner and technician. More convenient. More efficient.

• Puts the control of evaluating Holter studies directly into your hands. Provides time-stamped rhythm strip and summary report for your confirmation.

• Analyzes each heartbeat as it occurs; counts and categorizes arrhythmias in real time.

For a 15-minute, no obligation demonstration, call toll-free: 800-257-5750.

The Diagnosis and Treatment Oriented Approach to Rheumatology with the Primary Care Physician in Mind

Rheumatology

A Primary Care Approach

Written by:

Bruce M. Rothschild, MD

Director, Division of Rheumatology, University Health Sciences, The Chicago Medical School Chief, Section of Rheumatology, V. A. Medical Center North Chicago, Illinois

ISBN 0-914316-33-8 430 pp., illus., November 1982, $39.50

What is Rheumatology: A Primary Care Approach?

- a succinct (approx. 450 pp.) yet comprehensive presentation of the latest techniques in diagnosis and therapeutic interventions of most use to the primary care physician
- a practical "how-to" desk reference to a difficult but common disease affecting over 35 million patients in the U.S. alone
- a book meant to be used regularly, not read once and stored away on a library shelf
- the primary care physicians' answer to the huge, weighty tomes on Rheumatology which offer too little on diagnosis and treatment and too much on etiology and mechanisms of disease

Rheumatology: A Primary Care Approach is Not

- a research monograph filled with esoteric information of little use to the practicing primary care physician
- a difficult to follow, badly organized reference tool requiring a thorough knowledge of the subject matter before it can be used effectively
- a massive and verbose dissertation more useful as a door stop than a clinical reference

We know of no other book on rheumatic disease which covers the subject as exhaustively in terms of diagnosis and treatment while avoiding wasting the busy practitioner's time by including information of little interest to the primary care physician. This book emphasizes that information necessary to recognize basic disease processes and their natural history. It provides the reader with the information necessary for making a diagnosis and initiating a plan of treatment. Information on differential diagnosis from the point of view of characteristics which would not fit with a given diagnosis is also provided. It is especially strong on the interpretation of rheumatologic radiology and in its approach to joint examination and assessment of lab results. Rheumatic disease cannot be cured but proper intervention can reduce and sometimes eliminate the attendant disability. This book provides you with the means to diagnose, assess and decide for yourself the necessary intervention.

From the Preface:

"More than 15 million individuals in the United States suffer from arthritis, and there are only 3,000 physicians practicing rheumatology. It is evident that the majority of patients receive continuing care from the nonrheumatologist, i.e., the internist, family practitioner, pediatrician and other disciplines in medicine. Therefore, we require concise and authoritative clinical guidelines for the primary care physician. With this as motivation Dr. Bruce Rothschild has skillfully structured a text geared to the particular and immediate needs of the practitioner... This text... is an important contribution to continuing medical education of the clinician. It will be of immediate interest and value to clinicians in a wide variety of specialties and should be of great assistance to the faculties and student bodies of our medical schools. We have long needed this type of approach to primary care of patients with musculoskeletal diseases and we are indebted to the author for his accomplishments."

Alfred Soffer, MD

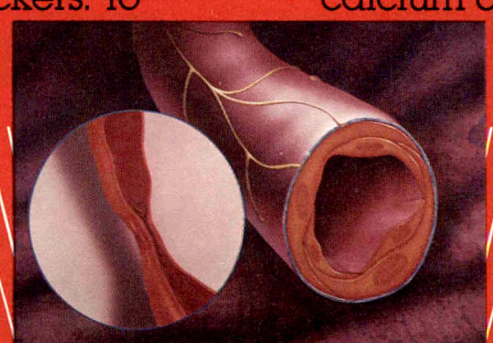
AJCG3

An educational program on new dimensions in the treatment of angina.*

CARDIZEM™ (diltiazem HCl): Calcium Channel Blockade in the Treatment of Coronary Heart Disease.

The CARDIZEM™ (diltiazem HCl) Educational Program will include a 30-minute film, with animated highlights depicting major aspects of the new class of drugs known as calcium channel blockers. To facilitate understanding of the use of calcium antagonists, a full monograph/self-test will accompany the film. Authorities in the fields of cardiology, pharmacology, and medicine will discuss the impact calcium channel blockers can make in the treatment of angina.



Please complete and mail this coupon for information.

Gentlemen:

I would like to arrange a showing of *CARDIZEM™ (diltiazem HCl): Calcium Chann Blockade in the Treatment of Coronary Hea Disease.*

Please cut along dotted line.
Mail to: Continuing Professional Education,

cardizem™ (diltiazem HCl)
30 mg and 60 mg tablets

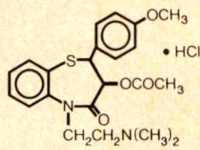
PHARMACEUTICAL DIVISION
MARION LABORATORIES, INC.
KANSAS CITY, MISSOURI 64137

PROFESSIONAL USE INFORMATION

cardizem™
(diltiazem HCl)
30 mg and 60 mg tablets

DESCRIPTION

CARDIZEM™ (diltiazem hydrochloride) is a calcium ion influx inhibitor (slow channel blocker or calcium antagonist). Chemically, diltiazem hydrochloride is 1,5-Benzothiazepin-4(5H)one,3-(acetyloxy)-5-[2-(dimethylamino)ethyl]-2,3-dihydro-2-(4-methoxyphenyl)-, monohydrochloride,(+) -cis-. The chemical structure is:



Diltiazem hydrochloride is a white to off-white crystalline powder with a bitter taste. It is soluble in water, methanol, and chloroform. It has a molecular weight of 450.98. Each tablet of CARDIZEM contains either 30 mg or 60 mg diltiazem for oral administration.

CLINICAL PHARMACOLOGY

The therapeutic benefits achieved with CARDIZEM are believed to be related to its ability to inhibit the influx of calcium ions during membrane depolarization of cardiac and vascular smooth muscle.

Mechanism of Action. Although precise mechanisms of its antianginal actions are still being delineated, CARDIZEM is believed to act in the following ways:

1. Angina Due to Coronary Artery Spasm: CARDIZEM has been shown to be a potent dilator of coronary arteries both epicardial and subendocardial. Spontaneous and ergonovine-induced coronary artery spasm are inhibited by CARDIZEM.
2. Exertional Angina: CARDIZEM has been shown to produce increases in exercise tolerance probably due to its ability to reduce myocardial oxygen demand. This is accomplished via reductions in heart rate and systemic blood pressure at submaximal and maximal exercise work loads.

In animal models, diltiazem interferes with the slow inward (depolarizing) current in excitable tissue. It causes excitation-contraction uncoupling in various myocardial tissues without changes in the configuration of the action potential. Diltiazem produces relaxation of coronary vascular smooth muscle and dilation of both large and small coronary arteries at drug levels which cause little or no negative inotropic effect. The resultant increases in coronary blood flow (epicardial and subendocardial) occur in ischemic and nonischemic models and are accompanied by dose-dependent decreases in systemic blood pressure and decreases in peripheral resistance.

Hemodynamic and Electrophysiologic Effects. Like other calcium antagonists, diltiazem decreases sinoatrial and atrioventricular conduction in isolated tissues and has a negative inotropic effect in isolated preparations. In the intact animal, prolongation of the AH interval can be seen at higher doses.

In man, diltiazem prevents spontaneous and ergonovine-provoked coronary artery spasm. It causes a decrease in peripheral vascular resistance and a modest fall in blood pressure and, in exercise tolerance studies in patients with ischemic heart disease, reduces the heart rate/blood pressure product for any given work load. Studies to date, primarily in patients with good ventricular function, have not revealed evidence of a negative inotropic effect; cardiac output, ejection fraction, and left ventricular end diastolic pressure have not been affected. There are as yet few data on the interaction of diltiazem and beta-blockers. Resting heart rate is usually unchanged or slightly reduced by diltiazem.

Intravenous diltiazem in doses of 20 mg prolongs AH conduction time and AV node functional and effective refractory periods approximately 20%. In a study involving single oral doses of 300 mg of CARDIZEM in six normal volunteers, the average maximum PR prolongation was 14% with no instances of greater than first-degree AV block. Diltiazem-associated prolongation of the AH interval is not more pronounced in patients with first-degree heart block. In patients with sick sinus syndrome, diltiazem significantly prolongs sinus cycle length (up to 50% in some cases).

Chronic oral administration of CARDIZEM in doses of up to 240 mg/day has resulted in small increases in PR interval, but has not usually produced abnormal prolongation. There were, however, three instances of second-degree AV block and one instance of third-degree AV block in a group of 959 chronically treated patients.

Pharmacokinetics and Metabolism. Diltiazem is absorbed from the tablet formulation to about 80% of a reference capsule and is subject to an extensive first-pass effect, giving an absolute bioavailability (compared to intravenous dosing) of about 40%. CARDIZEM undergoes extensive hepatic metabolism in which 2% to 4% of the unchanged drug appears in the urine. In vitro binding studies show CARDIZEM is 70% to 80% bound to plasma proteins. Competitive ligand binding studies have also shown CARDIZEM binding is not altered by therapeutic concentrations of digoxin, hydrochlorothiazide, phenylbutazone, propranolol, salicylic acid, or warfarin. Single oral doses of 30 to 120 mg of CARDIZEM result in detectable plasma levels within 30 to 60 minutes and peak plasma levels two to three hours after drug administration. The plasma elimination half-life following single or multiple drug administration is approximately 3.5 hours. Desacetyl diltiazem is also present in the plasma at levels of 10% to 20% of the parent drug and is 25% to 50% as potent as a coronary vasodilator as diltiazem. Therapeutic blood levels of CARDIZEM appear to be in the range of 50 to 200 ng/ml. There is a departure from dose-linearity when single doses above 60 mg are given; a 120-mg dose gave blood levels three times that of the 60-mg dose. There is no information about the effect of renal or hepatic impairment on excretion or metabolism of diltiazem.

INDICATIONS AND USAGE

1. **Angina Pectoris Due to Coronary Artery Spasm.** CARDIZEM is indicated in the treatment of angina pectoris due to coronary artery spasm. CARDIZEM has been shown effective in the treatment of spontaneous coronary artery spasm presenting as Prinzmetal's variant angina (resting angina with ST-segment elevation occurring during attacks).
2. **Chronic Stable Angina (Classic Effort-Associated Angina).** CARDIZEM is indicated in the management of chronic stable angina in patients who cannot tolerate therapy with beta-blockers and/or nitrates or who remain symptomatic despite adequate doses of these agents. CARDIZEM has been effective in short-term controlled trials in reducing angina frequency and increasing exercise tolerance, but confirmation of sustained effectiveness is incomplete.

There are no controlled studies of the effectiveness of the concomitant use of diltiazem and beta-blockers or of the safety of this combination in patients with impaired ventricular function or conduction abnormalities.

CONTRAINDICATIONS

CARDIZEM is contraindicated in (1) patients with sick sinus syndrome except in the presence of a functioning ventricular pacemaker, (2) patients with second- or third-degree AV block, and (3) patients with hypotension (less than 90 mm Hg systolic).

WARNINGS

1. **Cardiac Conduction.** CARDIZEM prolongs AV node refractory periods without significantly prolonging sinus node recovery time, except in patients with sick sinus syndrome. This effect may rarely result in abnormally slow heart rates (particularly in patients with sick sinus syndrome) or second- or third-degree AV block (4 of 959 patients for 0.42%). Concomitant use of diltiazem with beta-blockers or digitalis may result in additive effects on cardiac conduction. A patient with Prinzmetal's angina developed periods of asystole (2 to 5 seconds) after a single dose of 60 mg diltiazem.
2. **Congestive Heart Failure.** Although diltiazem has a negative inotropic effect in isolated animal tissue preparations, hemodynamic studies in humans with normal ventricular function have not shown a reduction in cardiac index nor consistent negative effects on contractility (dp/dt). Experience with the use of CARDIZEM alone or in combination with beta-blockers in patients with impaired ventricular function is very limited. Caution should be exercised when using the drug in such patients.
3. **Hypotension.** Decreases in blood pressure associated with CARDIZEM therapy may occasionally result in symptomatic hypotension.
4. **Acute Hepatic Injury.** There has been a single report in a patient receiving 120 mg of diltiazem t.i.d. of marked transaminase elevation (SGOT 4500, SGPT 2300) accompanied by hyperbilirubinemia (to 3 mg%), occurring after four days of treatment. The enzyme abnormalities resolved entirely, and enzymes were nearly normal a week after cessation of treatment. No rechallenge was carried out, but the patient had no evidence of viral hepatitis and received no other drugs but isosorbide dinitrate.

   No other similar liver injury has been reported in clinical trials, but marketing experience in Europe has resulted in a rechallenge-confirmed instance of hepatocellular injury. However, it should be noted that there have been further episodes of raised transaminases in the absence of diltiazem in this patient, so that the relationship to diltiazem of the abnormalities is not completely clear. Other instances of transaminase elevation have been reported in Europe, but their relationship to drug is uncertain.

PRECAUTIONS

General. CARDIZEM is extensively metabolized by the liver and excreted by the kidneys and in bile. As with any new drug given over prolonged periods, laboratory parameters should be monitored at regular intervals. The drug should be used with caution in patients with impaired renal or hepatic function. In subacute and chronic dog and rat studies designed to produce toxicity, high doses of diltiazem were associated with hepatic damage. In special subacute hepatic studies, oral doses of 125 mg/kg and higher in rats were associated with histological changes in the liver which were reversible when the drug was discontinued. In dogs, doses of 20 mg/kg were also associated with hepatic changes; however, these changes were reversible with continued dosing.

Drug Interaction. Pharmacologic studies indicate that there may be additive effects in prolonging AV conduction when using beta-blockers or digitalis concomitantly with CARDIZEM. (See WARNINGS.)

Uncontrolled domestic studies suggest that concomitant use of CARDIZEM and beta-blockers or digitalis is usually well tolerated. Available data are not sufficient, however, to predict the effects of concomitant treatment, particularly in patients with left ventricular dysfunction or cardiac conduction abnormalities; the effect of diltiazem on serum digoxin levels has not been examined. The safety of the combination of CARDIZEM and beta-blockers or digitalis is currently being investigated in well-controlled studies.

Carcinogenesis, Mutagenesis, Impairment of Fertility. A 24-month study in rats and a 21-month study in mice showed no evidence of carcinogenicity. There was also no mutagenic response in in vitro bacterial tests. No intrinsic effect on fertility was observed in rats.

Pregnancy. Category C. Reproduction studies have been conducted in mice, rats, and rabbits. Administration of doses ranging from five to ten times greater (on a mg/kg basis) than the daily recommended therapeutic dose has resulted in embryo and fetal lethality. These doses, in some studies, have been reported to cause skeletal abnormalities. In the perinatal/postnatal studies, there was some reduction in early individual pup weights and survival rates. There was an increased incidence of stillbirths at doses of 20 times the human dose or greater.

There are no well-controlled studies in pregnant women; therefore, use CARDIZEM in pregnant women only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers. It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk, exercise caution when CARDIZEM is administered to a nursing woman if the drug's benefits are thought to outweigh its potential risks in this situation.

Pediatric Use. Safety and effectiveness in children have not been established.

ADVERSE REACTIONS

Serious adverse reactions have been rare in studies carried out to date, but it should be recognized that patients with impaired ventricular function and cardiac conduction abnormalities have usually been excluded. Experience with an added beta-blocker is also extremely limited.

In domestic placebo-controlled trials, the incidence of adverse reactions reported during CARDIZEM therapy was not greater than that reported during placebo therapy.

In addition, the following have been reported infrequently and represent occurrences which can be at least reasonably associated with the pharmacology of calcium influx inhibition. In many cases, the relationship to CARDIZEM has not been established. The most common occurrences, as well as their frequency of presentation, are nausea (2.7%), swelling/edema (2.4%), arrhythmia (2.0%), headache (2.0%), rash (1.8%), and fatigue (1.1%). In addition, the following events were reported infrequently (<1.0%). The order of presentation corresponds to the relative frequency of occurrence.

Cardiovascular:	Flushing, congestive heart failure, bradycardia, hypotension, syncope, pounding heart.
Central Nervous System:	Drowsiness, dizziness, lightheadedness, nervousness, depression, weakness, insomnia, confusion, hallucinations.
Gastrointestinal:	Vomiting, diarrhea, gastric upset, constipation, indigestion, pyrosis.
Dermatologic:	Pruritus, petechiae, urticaria.
Other:	Photosensitivity, nocturia, thirst, paresthesias, polyuria, osteoarticular pain.

The following additional experiences have been noted:

A patient with Prinzmetal's angina experiencing episodes of vasospastic angina developed periods of transient asymptomatic asystole approximately five hours after receiving a single 60-mg dose of CARDIZEM.

Experience in 959 patients taking oral doses of CARDIZEM resulted in three cases (0.31%) of second-degree AV block and one case (0.10%) of third-degree AV block at doses of 240 to 360 mg daily.

In rare instances, mild to moderate transient elevations of alkaline phosphatase, SGOT, SGPT, LDH, and CPK have been noted during CARDIZEM therapy. A single incident of markedly elevated liver enzymes associated with symptoms was reported in a patient taking 360 mg per day for four days. Drug was discontinued and enzymes normalized within 1 week.

OVERDOSAGE OR EXAGGERATED RESPONSE

Overdosage experiences with oral diltiazem have not been reported. Single oral doses of 300 mg of CARDIZEM have been well tolerated by healthy volunteers. In the event of overdosage or exaggerated response, appropriate supportive measures should be employed in addition to gastric lavage. The following measures may be considered:

Bradycardia	Administer atropine (0.60 to 1.0 mg). If there is no response to vagal blockade, administer isoproterenol cautiously.
High-Degree AV Block	Treat as for bradycardia above. Fixed high-degree AV block should be treated with cardiac pacing.
Cardiac Failure	Administer inotropic agents (isoproterenol, dopamine, or dobutamine) and diuretics.
Hypotension	Vasopressors (eg, dopamine or levarterenol bitartrate).

Actual treatment and dosage should depend on the severity of the clinical situation and the judgment and experience of the treating physician.

The oral LD_{50}'s in mice and rats range from 415 to 740 mg/kg and from 560 to 810 mg/kg, respectively. The intravenous LD_{50}'s in these species were 60 and 38 mg/kg, respectively. The oral LD_{50} in dogs is considered to be in excess of 50 mg/kg, while lethality was seen in monkeys at 360 mg/kg. The toxic dose in man is not known, but blood levels in excess of 800 ng/ml have not been associated with toxicity.

DOSAGE AND ADMINISTRATION

Exertional Angina Pectoris Due to Atherosclerotic Coronary Artery Disease or Angina Pectoris at Rest Due to Coronary Artery Spasm. Dosage must be adjusted to each patient's needs. Starting with 30 mg four times daily, before meals and at bedtime, dosage should be increased gradually to 240 mg (given in divided doses three or four times daily) at one- to two-day intervals until optimum response is obtained. The effectiveness and safety of dosages exceeding 240 mg per day are currently being investigated. There are no available data concerning dosage requirements in patients with impaired renal or hepatic function. If the drug must be used in such patients, titration should be carried out with particular caution.

Concomitant Use With Other Antianginal Agents.

1. **Sublingual NTG** may be taken as required to abort acute anginal attacks during CARDIZEM therapy.
2. **Prophylactic Nitrate Therapy**—CARDIZEM may be safely coadministered with short- and long-acting nitrates, but there have been no controlled studies to evaluate the antianginal effectiveness of this combination.
3. **Beta-blockers.** (See WARNINGS and PRECAUTIONS.)

HOW SUPPLIED

CARDIZEM 30-mg tablets are supplied in bottles of 100 (NDC 0088-1771-47). Each green tablet is engraved with MARION on one side and 1771 engraved on the other. CARDIZEM 60-mg scored tablets are supplied in bottles of 100 (NDC 0088-1772-47). Each yellow tablet is engraved with MARION on one side and 1772 on the other.

Cordis Implantable Pacers and Programmers

Indications and Contraindications
The medical literature describes currently accepted indications and contraindications for the various pacing/sensing modes. However, the physician's clinical experience and judgment must ultimately determine the pacing mode best suited to the patient's needs.

When spontaneous beats are expected, a sensing mode (inhibited or triggered) is indicated. *Asynchronous pacing is contraindicated for long-term pacing when inherent activity is present or likely to be present in the chamber being paced.*

Pacing of the ventricles (VVI or VVT) is indicated for controlling slow heart rate in patients with A-V block and/or sick sinus syndrome. Atrial pacing (AAI or AAT) is indicated for controlling heart rate, increasing cardiac output, and suppressing premature ventricular contractions (PVCs) in patients with intact A-V conduction and sick sinus syndrome. *Atrial pacing is contraindicated when A-V conduction disturbances are present.*

Atrial-synchronized ventricular pacing (VVD or VAT) and dual-chamber pacing (DVI or DDD) are indicated for patients who would benefit from restoration of atrial contribution to cardiac output and the control of heart rate. Atrial-synchronized ventricular pacing is indicated for patients with permanent heart block and normal atrial rhythm. Dual-chamber pacing is indicated for A-V conduction disturbances with sinus node dysfunction (sinus bradycardia with A-V block, bradytachy syndrome). *Atrial-synchronized ventricular pacing and automatic dual-chamber demand pacing modes are contraindicated in the presence of persistent atrial flutter or atrial fibrillation.* The VVI mode is recommended for these conditions.

Cordis programmers are designed to noninvasively control the operating parameters and modes of Cordis programmable cardiac pacers.

Precautions
Cordis implantable pacers may respond to programmers of other manufacturers. Because of the unknown nature of such response, use only the Cordis Model 255A Programmer III for reprogramming.

Use pacers on a first-in, first-out basis prior to the "Use before" date on the package.

Warnings
None

Adverse Effects
A number of complications related to pacer therapy have been reported in the medical literature. The complications listed below may occur at any time after implantation.

Pacer – battery depletion, electromagnetic interference, component malfunction, decreased sensitivity.

Lead – unsatisfactory electrode position, fracture, displacement, perforation of heart wall, faulty connection with pacer, migration through body tissue.

Patient – reaction, infection/erosion, increase in stimulation threshold, embolism, thrombosis.

Caution: Federal (U.S.A.) law restricts these devices to sale by or on the order of a physician.

Prior to use, refer to the *Instructions for Use* for more information.

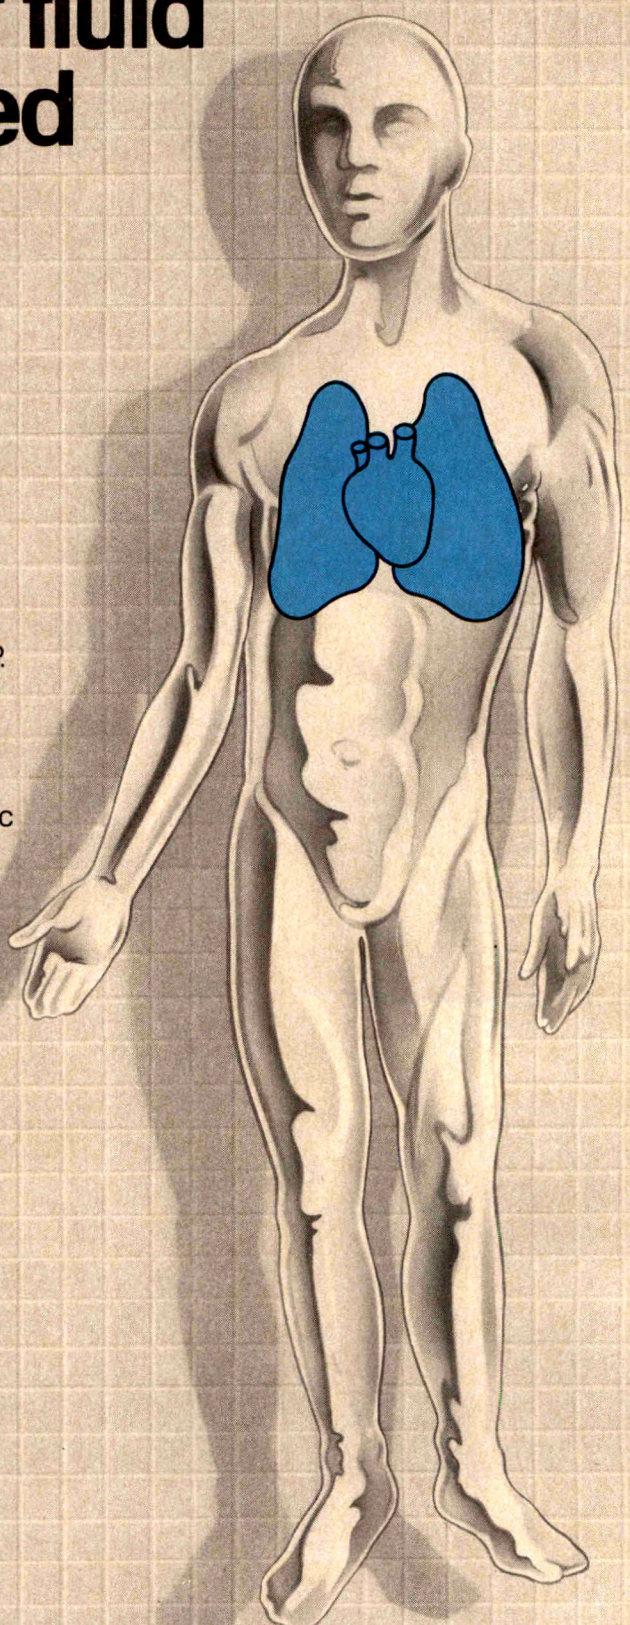
A familiar name in medicine becomes

Therapeutic challenge:

Redistribution of fluid in CHF associated with acute MI



In Early CHF[1]

Pulmonary congestion with increased preload.

Findings: Elevated preload, elevated blood pressure, normal or slightly decreased cardiac output, PCWP greater than or equal to 18 mm Hg.

Therapeutic goal:
Reduce pulmonary congestion, lower PCWP to 15 to 18 mm Hg.

In Late CHF[1]

Pulmonary congestion with increased preload and afterload.

Findings: Low cardiac output, depressed blood pressure, and high PCWP.

Therapeutic goal:
Reduce pulmonary congestion, preload, and afterload, increase cardiac output, and lower PCWP to 15 to 18 mm Hg.

Why wait for the patient to become unresponsive to traditional diuretic/digitalis therapy?

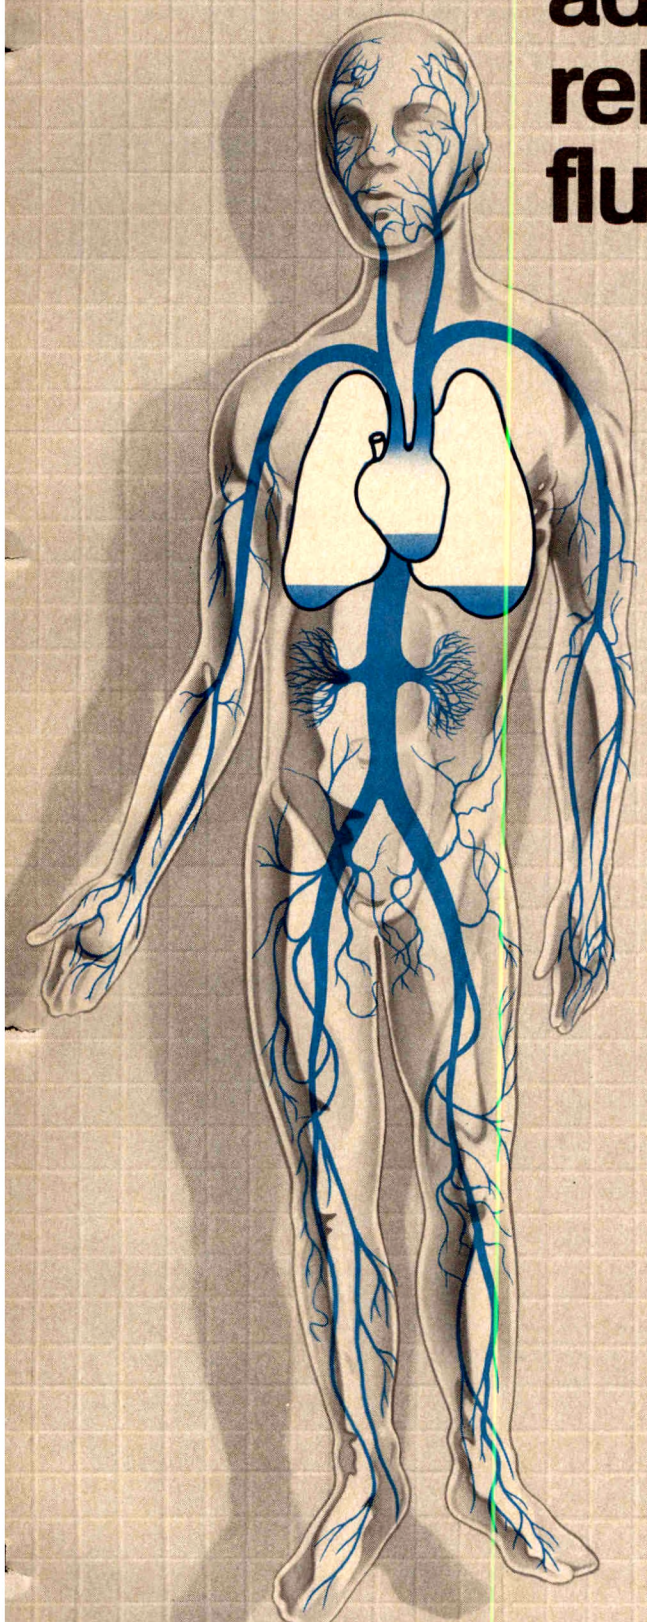
Give Tridil® (nitroglycerin) adjunctively to help relieve the fluid-burdened heart



In a dose-related manner, Tridil produces dilation of both arterial and venous beds—for a therapeutic redistribution of fluid.

Suggested therapy in early CHF

If blood pressure is normal:
Tridil to reduce preload and PCWP. Diuretics to decrease fluid volume.

If blood pressure is elevated:
Tridil should be initiated immediately to decrease preload, PCWP, and blood pressure, while maintaining coronary perfusion.

Suggested therapy in late CHF

If blood pressure is normal or only moderately depressed:
Vasopressors and Tridil adjunctively, with continuous hemodynamic monitoring.

If blood pressure is significantly depressed:
Vasopressors and Tridil adjunctively to reduce preload, afterload, and PCWP. Dopamine to increase the contractility of the myocardium. PCWP should be monitored.

Use of nonabsorbing Tridilset®

Sorptive loss of Tridil may range up to 80% when infused through a conventional PVC administration set[2] To overcome this problem, administer Tridil through Tridilset administration set or Tridilset V.I.P.™ volumetric pump connector set.

The most frequent adverse reaction in patients treated with Tridil is headache. Please see the following page for a brief summary of prescribing information. Note: Tridil is a potent drug and must be diluted before infusion.

For additional information, contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 312/473-3000.

TRIDIL® (nitroglycerin) SYSTEM

American Critical Care

TRIDIL® (nitroglycerin)

Brief Summary of Full Prescribing Information

NOT FOR DIRECT INTRAVENOUS INJECTION. TRIDIL® MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION (SEE DOSAGE AND ADMINISTRATION SECTION OF FULL PRESCRIBING INFORMATION). THE ADMINISTRATION SET USED FOR INFUSION WILL AFFECT THE AMOUNT OF TRIDIL DELIVERED TO THE PATIENT. (SEE WARNINGS, AND DOSAGE AND ADMINISTRATION SECTIONS.)

CAUTION

SEVERAL PREPARATIONS OF NITROGLYCERIN FOR INJECTION ARE AVAILABLE. THEY DIFFER IN CONCENTRATION AND/OR VOLUME PER VIAL. WHEN SWITCHING FROM ONE PRODUCT TO ANOTHER ATTENTION MUST BE PAID TO THE DILUTION AND DOSAGE AND ADMINISTRATION INSTRUCTIONS.

CONTRAINDICATIONS

TRIDIL should not be administered to individuals with:

1. A known hypersensitivity to nitroglycerin or a known idiosyncratic reaction to organic nitrates.
2. Hypotension or uncorrected hypovolemia, as the use of TRIDIL in such states could produce severe hypotension or shock.
3. Increased intracranial pressure (e.g., head trauma or cerebral hemorrhage).
4. Constrictive pericarditis and pericardial tamponade.

WARNINGS

1. Nitroglycerin readily migrates into many plastics. To avoid absorption of nitroglycerin into plastic parenteral solution containers, the dilution and storage of TRIDIL for intravenous infusion should be made only in *glass* parenteral solution bottles.
2. Some filters absorb nitroglycerin; they should be avoided.
3. Forty to 80% of the total amount of nitroglycerin in the final diluted solution for infusion is absorbed by the polyvinyl chloride (PVC) tubing of the intravenous administration sets currently in general use. The higher rates of absorption occur when flow rates are low, nitroglycerin concentrations are high, and the administration set is long. Although the rate of loss is highest during the early phase of infusion (when flow rates are lowest) the loss is neither constant nor self-limiting; consequently no simple calculation or correction can be performed to convert the theoretical infusion rate (based on the concentration of the infusion solution) to the actual delivery rate.

Because of this problem, American Critical Care has developed TRIDILSET,® an administration set in which loss of TRIDIL is minimal (less than 1%). TRIDILSET (or a similar administration set) is recommended for infusions of TRIDIL.

DOSING INSTRUCTIONS MUST BE FOLLOWED WITH CARE. IT SHOULD BE NOTED THAT WHEN TRIDILSET IS USED, THE CALCULATED DOSE WILL BE DELIVERED TO THE PATIENT BECAUSE THE LOSS OF TRIDIL DUE TO ABSORPTION IN STANDARD PVC TUBING WILL BE KEPT TO A MINIMUM. NOTE THAT THE DOSAGES COMMONLY USED IN PUBLISHED STUDIES UTILIZED GENERAL-USE PVC ADMINISTRATION SETS AND RECOMMENDED DOSES BASED ON THIS EXPERIENCE ARE TOO HIGH WHEN TRIDILSET IS USED.

PRECAUTIONS

TRIDIL (nitroglycerin) should be used with caution in patients with severe liver or renal disease.

Excessive hypotension, especially for prolonged periods of time, must be avoided because of possible deleterious effects on the brain, heart, liver, and kidney from poor perfusion and the attendant risk of ischemia, thrombosis, and altered function of these organs. Paradoxical bradycardia and increased angina pectoris may accompany nitroglycerin-induced hypotension. Patients with normal or low pulmonary capillary wedge pressure are especially sensitive to the hypotensive effects of TRIDIL. If pulmonary capillary wedge pressure is being monitored, it will be noted that a fall in wedge pressure precedes the onset of arterial hypotension, and the pulmonary capillary wedge pressure is thus a useful guide to safe titration of the drug.

Carcinogenesis, mutagenesis, impairment of fertility

No long-term studies in animals were performed to evaluate carcinogenic potential of TRIDIL.

Pregnancy

Category C. Animal reproduction studies have not been conducted with TRIDIL. It is also not known whether TRIDIL can cause fetal harm when administered to a pregnant woman or can affect reproduction capacity. TRIDIL should be given to a pregnant woman only if clearly needed.

Nursing Mothers

It is not known whether nitroglycerin is excreted in human milk. Because many drugs are excreted in human milk, caution should be exercised when TRIDIL is administered to a nursing woman.

Pediatric Use

The safety and effectiveness of TRIDIL in children have not been established.

ADVERSE REACTIONS

The most frequent adverse reaction in patients treated with TRIDIL is headache, which occurs in approximately 2% of patients. Other adverse reactions occurring in less than 1% of patients are the following: tachycardia, nausea, vomiting, apprehension, restlessness, muscle twitching, retrosternal discomfort, palpitations, dizziness and abdominal pain.

The following additional adverse reactions have been reported with the oral and/or topical use of nitroglycerin: cutaneous flushing, weakness, and occasionally drug rash or exfoliative dermatitis.

OVERDOSAGE

Accidental overdosage of TRIDIL may result in severe hypotension and reflex tachycardia which can be treated by elevating the legs and decreasing or temporarily terminating the infusion until the patient's condition stabilizes. Since the duration of the hemodynamic effects following TRIDIL administration is quite short, additional corrective measures are usually not required. However, if further therapy is indicated, administration of an intravenous alpha adrenergic agonist (e.g., methoxamine or phenylephrine) should be considered.

DOSAGE AND ADMINISTRATION

(For complete information, please see Full Prescribing Information)

NOT FOR DIRECT INTRAVENOUS INJECTION

TRIDIL IS A CONCENTRATED, POTENT DRUG WHICH MUST BE DILUTED IN DEXTROSE (5%) INJECTION, USP OR SODIUM CHLORIDE (0.9%) INJECTION, USP PRIOR TO ITS INFUSION. TRIDIL SHOULD NOT BE ADMIXED WITH OTHER DRUGS.

Some patients with normal or low left ventricular filling pressures or pulmonary capillary wedge pressure (e.g., angina patients without other complications) may be hypersensitive to the effects of TRIDIL and may respond fully to doses as small as 5 mcg/min. These patients require especially careful titration and monitoring.

There is no fixed optimum dose of TRIDIL. Due to variations in the responsiveness of individual patients to the drug, each patient must be titrated to the desired level of hemodynamic function. Therefore, continuous monitoring of physiologic parameters (e.g., blood pressure and heart rate in all patients, other measurements such as pulmonary capillary wedge pressure, as appropriate), MUST BE PERFORMED to achieve the correct dose. Adequate systemic blood pressure and coronary perfusion pressure must be maintained.

HOW SUPPLIED

NDC 0094-0090-05, 25 mg-5 ml ampul. NDC 0094-0090-10, 50 mg-10 ml ampul. Each ml contains 5 mg nitroglycerin. Protect from freezing.

MYOCARDIAL REVASCULARIZATION

MEDICAL AND SURGICAL ADVANCES IN CORONARY DISEASE

The most up-to-date reference on the state of the art of medical and surgical myocardial revascularization in clinical coronary disease available today.

Written by 130 selected authorities, MYOCARDIAL REVASCULARIZATION represents the first comprehensive coverage of the subject, presenting many new therapeutic modalities not previously published anywhere. This volume is an outgrowth of the recent International Symposium on Myocardial Revascularization held in Nassau, The Bahamas. It is edited by two internationally renowned specialists, Dean T. Mason, MD, and John J. Collins, Jr., MD.

Myocardial Revascularization features the latest on:

- Streptokinase - Thrombolysis in AMI (Percutaneous Transluminal Coronary Recanalization (PTCR)
- Percutaneous Transluminal Coronary Angioplasty (PTCA)
- New Calcium Blocking Drugs
- Cardiac Benefits of Coronary Rehabilitation Programs
- Coronary Bypass Surgery for Angina, Unstable Angina, AMI

Platelet Alpha$_2$ Adrenoreceptors in Chronic Congestive Heart Failure

ROBERT J. WEISS, MD, MICHAEL TOBES, PhD, CURTIS E. WERTZ, BA, and CHARLES B. SMITH, MD, PhD

Patients with chronic congestive heart failure (CHF) are known to have elevated plasma concentrations of norepinephrine. Although this elevation of catecholamines in plasma may facilitate myocardial contractility, it may also be toxic to the myocardium in the long term. The alpha$_2$ adrenoreceptor located on noradrenergic nerve terminals regulates neuronal norepinephrine release by feedback inhibition. This receptor is also located on human blood platelets. This study determines the status of platelet alpha$_2$ adrenoreceptors in 16 patients with CHF (class I and II in 7 and class III and IV in 9) and in 26 normal volunteers. Specific high-affinity binding of the alpha$_2$ agonist ^{3}H-clonidine and the alpha$_2$ antagonist ^{3}H-yohimbine was used to determine the number (B_{max}) of alpha$_2$ receptors and the dissociation constant (K_D) for the 2 ligands. In the control population, the B_{max} (in fmol/mg protein) for ^{3}H-clonidine was 33 ± 2 and for ^{3}H-yohimbine was 165 ± 12. There was a 25% difference in the maximum number of specific binding sites for ^{3}H-clonidine in the class III/IV group (B_{max} 24 ± 2, $p < 0.05$) and a 43% difference in the maximum number of specific binding sites for ^{3}H-yohimbine (B_{max} 94 ± 9; $p < 0.005$). There was a smaller but nonsignificant difference in the number of receptors on platelets from patients in the class I and II group. The K_D's were similar in all 3 groups. These differences correlated well with the increases in plasma norepinephrine levels between the normal group (273.8 ± 44.1 pg/ml) and the class III/IV group (1333.5 ± 244.9, $p < 0.0005$). This study supports the hypothesis that increased levels of circulating norepinephrine in CHF lead to a decrease in platelet alpha$_2$ adrenoreceptors. Further studies should be performed to determine whether pharmacologic stimulation of these receptors might lead to a decrease in the neuronal release of that norepinephrine which might be toxic to the myocardium. Monitoring of platelet alpha$_2$ adrenoreceptor number may provide a guide to therapy of CHF.

Patients with chronic congestive heart failure (CHF) are known to have elevated concentrations of circulating norepinephrine. The degree of elevation is related to the degree of left ventricular dysfunction.[1–3] Although the circulating norepinephrine may increase myocardial contractility, persistently elevated levels have been shown to be toxic to the myocardium in experimental animals[4–6] and in humans.[7,8]

The alpha$_2$ adrenoreceptor is located presynaptically on noradrenergic nerve terminals and has been shown to exert a negative feedback inhibition upon norepinephrine release when stimulated.[9–11] If neurogenically released norepinephrine has a detrimental effect on the myocardium, alterations in alpha$_2$ adrenoreceptor function might be of potential importance in CHF. Human blood platelets have been suggested as a model for the indirect study of changes in nerve cell function.[12] Studies which use receptor binding techniques and which measure the relative order of potencies of various adrenergic agonists and antagonists in displacing bound radioligand have shown that human platelets have alpha$_2$ adrenoreceptors similar to those present on noradrenergic nerve terminals.[13,14] Changes in the number and affinity of alpha$_2$ adrenoreceptor binding sites in the rat brain after various interventions have been well correlated with similar changes on human blood platelets.[14–17] These have also been correlated with changes in norepinephrine release and tension developed in field stimulation experiments upon isolated rat atrial strips.[18]

From the Departments of Pharmacology and Internal Medicine, University of Michigan Medical School, Ann Arbor, Michigan. Address for reprints: Charles B. Smith, MD, PhD, Department of Pharmacology, University of Michigan Medical School, Ann Arbor, Michigan 48109.

The hypothesis of the present study was that alpha$_2$ adrenoreceptors on human blood platelets would be decreased by the increased circulating levels of norepinephrine found in severe chronic CHF and as such mirror changes found in the presynaptic site.

Methods

Patient population: Blood was obtained by venipuncture from healthy male and female volunteers (mean age 40 ± 3 years, n = 26). These control subjects were compared with patients with chronic CHF who were selected and classified by history, physical examination, and invasive hemodynamic monitoring findings. The patients were divided into standard New York Heart Association[19] class I and II (Group 1: mean age 62 ± 2 years, n = 7) and class III and IV groups (Group 2: mean age 68 ± 4 years, n = 9). The cause of the CHF was valvular (Group 1 = 3, Group 2 = 2), ischemic (Group 1 = 3, Group 2 = 5), and idiopathic (Group 1 = 1, Group 2 = 2). The 2 groups did not differ in the distribution of causes. Previous work[16] has shown the lack of age or sex dependency of either the total number or the affinity of platelet alpha$_2$ adrenoreceptors. None of the patients were taking alpha-adrenergic agonists or antagonists, indirectly acting adrenergic drugs, or inhibitors of norepinephrine uptake for at least 1 month before the study.

Written informed consent was obtained from all patients. This study was approved by the University of Michigan's Institutional Review Board. All assays were done without the knowledge of the patient's clinical characteristics.

Isolation of platelet membranes and radioligand binding assay: Platelet membranes were obtained by the method described by Garcia-Sevilla et al.[14] Briefly, 50 ml of blood was collected in polyethylene tubes which contained acid-citrate dextrose (ACD, 8:1, volume/volume). The blood was centrifuged at 160 *g* for 10 minutes (25°C), and the platelet-rich plasma was titrated to pH 6.5 with the ACD solution. This was then recentrifuged at 5,100 *g* for 15 minutes (25°C) to obtain a platelet pellet. The pellet was washed twice with 5 ml of Tyrode's buffer (m*M* concentrations: sodium chloride 137, potassium chloride 2.7, sodium biphosphate 0.36, magnesium chloride 0.10, sodium bicarbonate 12.0, dextrose 0.56, pH 8.0) and recentrifuged for 15 minutes at 5,100 *g*. The pellet was lysed by homogenization in 2 ml of ice-cold hypotonic buffer (Tris-EDTA, 5 m*M*, pH 7.5). The platelet membranes were obtained by centrifugation at 39,000 *g* for 10 minutes and then resuspended in the Tris incubation buffer (m*M*: Tris-hydrochloric acid 50, magnesium chloride 10, pH 7.5) used in the binding assay.

Total binding of ^{3}H-clonidine, an alpha$_2$-adrenoreceptor agonist, and of ^{3}H-yohimbine, an alpha$_2$-adrenoreceptor antagonist (New England Nuclear, Boston, Massachusetts) was measured in 1 ml aliquots of the fresh platelet membranes (0.254 ± 0.054 mg protein) which were incubated in duplicate at 25°C for 20 minutes with the radioligand. Nonspecific binding was determined by adding unlabelled clonidine or yohimbine (10^{-5} *M*), in addition to the respective tritiated ligand, to a second pair of incubates. Specific binding was

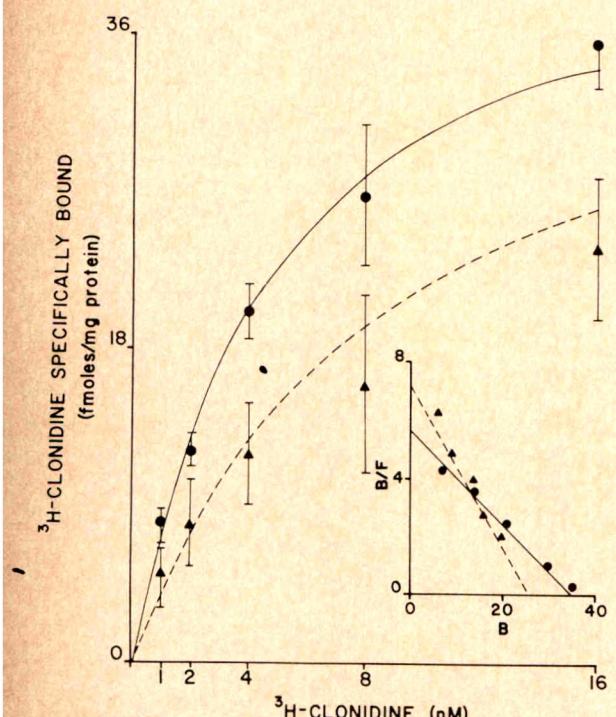

FIGURE 1. Specific binding of ^{3}H-clonidine to platelet membranes from normal subjects (**solid line**) and from patients with class III and IV congestive heart failure (**dashed line**) as a function of increasing concentrations (1 to 64 n*M*) of the ligand. **Ordinate,** ^{3}H-clonidine specifically bound (fmol/mg protein). **Abscissa,** concentration of ^{3}H-clonidine (n*M*). **Inset,** Scatchard plot showing the change in number of the high affinity binding site (normal subjects: B_{max} = 33 ± 2 fmol/mg protein, K_D = 5.5 ± 0.6 n*M* versus class III and IV: B_{max} = 24 ± 2, K_D = 3.4 ± 0.6 n*M*; $p < 0.05$). Results are expressed as the mean ± standard error of the mean. B = specifically bound ligand; B/F = specifically bound ligand/free ligand.

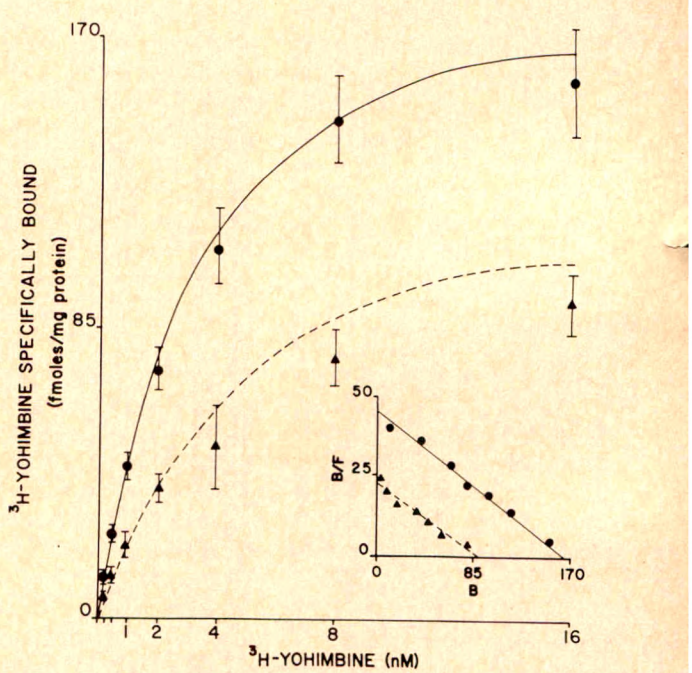

FIGURE 2. Specific binding of ^{3}H-yohimbine to platelet membranes from normal subjects (**solid line**) and from patients with class III and IV congestive heart failure (**dashed line**) as a function of increasing concentrations (0.25 to 16 n*M*) of the ligand. **Ordinate,** ^{3}H-yohimbine specifically bound (fmol/mg protein). **Abscissa,** concentration of ^{3}H-yohimbine (n*M*). **Inset,** Scatchard plot showing the change in number of the single binding site (normal subjects: B_{max} = 165 ± 12 fmol/mg protein, K_D = 4.0 ± 0.5 n*M* versus class III and IV: B_{max} = 94 ± 9, K_D = 4.4 ± 0.4; $p < 0.005$). Results are expressed as the mean ± standard error of the mean. B = specifically bound ligand; B/F = specifically bound ligand/free ligand.

defined as the difference between total and nonspecific binding. Incubations were terminated by adding 5 ml of the Tris incubation buffer to the sample. The membrane-bound tritiated ligand was recovered by rapid filtration of the diluted sample under vacuum through Whatman GF/C glass fiber filters. The filters were washed with two 10 ml aliquots of Tris incubation buffer (25°C). The filters were air dried and counted for radioactivity as described by Smith et al.[20] Proteins were determined by the method of Lowry et al.[21]

Catecholamine determination: Catecholamine determinations were performed by the radioenzymatic assay of Passon and Peuler.[22] The rat liver catechol-O-methyltransferase (COMT) was prepared according to the method of Axelrod and Tomchick.[23] All blood samples were collected as described above with the patient recumbent for at least 30 minutes. The samples were immediately centrifuged and the serum was frozen at −70°C.

Statistical analysis: Student's *t* test was used to test for the significance of differences. The level of significance was $p < 0.05$. Correlation coefficients for the binding isotherms were obtained by linear regression analysis which uses the method of least squares.

Results

Binding data: The specific binding of both ^{3}H-clonidine and ^{3}H-yohimbine to platelet membranes from both normal subjects and patients with chronic CHF was both saturable and of high affinity (Fig. 1 and 2). Scatchard analysis of the saturation isotherms again confirmed previous observations[15] that there was no correlation between age or sex and the total number of binding sites (B_{max}) or the affinity (K_D) of the radioligand for the site. The individual data for the control population for ^{3}H-clonidine (n = 26) was $B_{max} = 33 \pm 2$ and $K_D = 5.5 \pm 0.6$, and for ^{3}H-yohimbine (n = 16) was $B_{max} = 165 \pm 12$, and $K_D = 4.0 \pm 0.5$. There was no difference in the means for either ligand when the over 60-year-old subgroup was compared with the under 60-year-old group.

Patients with the more severe CHF, class III and IV (n = 9, Table I) had a 25% decrease in the maximum number of ^{3}H-clonidine binding sites compared with control subjects ($B_{max} = 24 \pm 2$, $p < 0.05$, Fig. 1) with no change in affinity ($K_D = 3.4 \pm 0.6$, difference not significant). There was also a marked decrease in the B_{max} for ^{3}H-yohimbine (43%, $B_{max} = 94 \pm 9$, $p < 0.005$) but no change in the affinity of the ligand for the receptor ($K_D = 4.4 \pm 0.4$, Fig. 2). Patients with class I and II chronic CHF (n = 7, Table II) had binding data with ^{3}H-yohimbine that suggested a trend towards a decrease in B_{max} as compared with normal subjects ($B_{max} = 133 \pm 16$). This was not statistically significant. In this group, there were not enough studies done with ^{3}H-clonidine to analyze.

Plasma catecholamines: Plasma norepinephrine, epinephrine, and dopamine levels were measured in all control subjects and patients. In normal subjects, the norepinephrine value was 273.8 ± 44.1 pg/ml (range 54 to 503). There was a statistically significant increase in norepinephrine levels in patients with class I and II CHF (628.7 ± 97.6 pg/ml, range 338 to 1079; $p < 0.005$) with a far more significant increase in patients with class III and IV CHF (1333.5 ± 244.9 pg/ml, range 642 to 3142; $p < 0.0005$).

There was no significant difference in plasma epinephrine concentration between normal subjects and class I and II patients (normals 57.0 ± 17.4 pg/ml, class I and II 95.0 ± 48.7). Plasma epinephrine level was elevated significantly in patients with class III and IV CHF (117.1 ± 32.0, $p < 0.05$). Although there was no significant difference in plasma dopamine concentration between the normal group (12.5 ± 9.9 pg/ml) and the class I and II CHF group (38.5 ± 19.6), there also was a statistically significant increase in the class III and IV group (94.1 ± 31.1, $p < 0.01$).

There was a striking relationship for each group between an elevated level of plasma norepinephrine and a decrease in the total number of binding sites for the tritiated ligand (Fig. 3).

Discussion

The ^{3}H-clonidine binding site on human platelets has been characterized as an alpha$_2$-adrenoreceptor site similar to that located presynaptically.[13,14] Stimulation of alpha$_2$ presynaptic receptors[24,25] inhibits neurotransmitter release during nerve stimulation, whereas inhibition of the site increases the overflow of norepinephrine after nerve stimulation.

Although a recent review[26] suggested that the number of alpha$_2$ adrenoreceptors on human platelets as determined by ^{3}H-yohimbine binding is not subject to down-regulation, data presented here suggest this is not the case. The total number of binding sites, B_{max}, as defined by ^{3}H-yohimbine binding, was 43% less in the class III and IV CHF patients and 19% less in the class I and II patients as compared with normal subjects. This was statistically significant for the class III and IV patients ($p < 0.0005$). Changes of a similar magnitude were also noted using ^{3}H-clonidine as the radioligand (class III and IV 25%, $p < 0.05$). Other work from our laboratory[14] has shown significant increases in the number of platelet alpha$_2$ adrenoreceptors in other settings, such as a group of depressed patients versus a normal control population. Treatment with tricyclic antidepressants[14] or with electroconvulsive shock therapy[16] led to a significant decrease in the number of these binding sites. These changes are mirrored by changes in the presynaptic alpha$_2$ adrenoreceptor in the rat brain after identical interventions.[17] It has been suggested that changes in receptor number may not be of physiologic importance.[26] Again, work in our laboratory has correlated decreases in alpha$_2$-adrenoreceptor number in rat brain after long-term tricyclic antidepressant drug treatment[18] with increased norepinephrine release from adrenergic neurons in the isolated rat left atrium.[18]

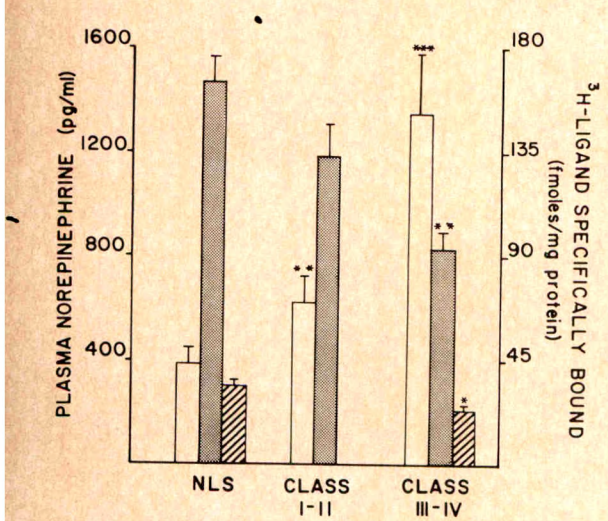

FIGURE 3. Relationship of plasma norepinephrine levels (**open bars**) and the maximum number of ^{3}H-yohimbine (**shaded bars**) and ^{3}H-clonidine (**cross-hatched bars**) binding sites. * $p < 0.05$, ** $p < 0.005$, *** $p < 0.0005$ (between control group and group with class III/IV failure). NLS = normal subjects.

Further evidence of the physiologic importance of this decrease in the number of presynaptic receptors in patients with severe congestive failure may be found in the recent work by Swedberg et al.[27] They defined a correlation between myocardial norepinephrine release and the stroke work index. As left ventricular function decreased, there was an increase in norepinephrine released, as measured by the arterial-coronary sinus difference. In our study, a decrease in left ventricular function was associated with fewer alpha$_2$ adrenoreceptors, a condition which would permit increased neuronal norepinephrine release.

Older work by Covell et al,[28] however, was interpreted as not suggesting increased neuronal release of norepinephrine in CHF. They showed that stimulation of the right cardio-accelerans nerve in the dog produced sharply diminished increases in heart rate and right ventricular contractile force in animals with right heart failure versus normal control animals. In addition, they showed that the myocardial response to exogenous norepinephrine was unchanged from normal values, which suggested to them that the quantity of neurotransmitter released per nerve impulse was reduced in their experimental model of heart failure. That the cardiac norepinephrine depletion found in chronic CHF did not affect the contractile function of cardiac muscle was shown with cat papillary muscle isolated from chronically denervated heart[29] and with isolated rat hearts.[30] One would have, perhaps, expected increased release of norepinephrine with the decrease in number of platelet alpha$_2$ adrenoreceptors. This inconsistency may possibly be explained by a decrease in cardiac stores of norepinephrine in CHF,[31–33] a defect in binding or synthesis of catecholamines in congestive failure,[34] or by a decrease in tyrosine hydroxylase activity.[35] Although it is believed that the platelet alpha$_2$ adrenoreceptor "down-regulates" in response to the high plasma concentrations of norepinephrine, it is possible that any similar change in the neuronal receptors in the

myocardium may occur in order to permit an increase in norepinephrine release. The increased release of catecholamine would permit increased inotropic support of the failing myocardium. That different tissues may respond differently in CHF has been suggested by data which showed decreased myocardial norepinephrine stores in light of normal renal stores.[32]

In our study, there was a significant increase in plasma norepinephrine levels in patients with class III and IV CHF versus those of normal volunteers ($p < 0.0005$) and also in those with only class I or II CHF ($p < 0.005$). Although the blood samples were obtained by venipuncture and not through an indwelling catheter, previous work suggests this does not affect the plasma norepinephrine concentration.[36] These values are consistent with previously reported studies[1,4,5] which correlated an elevated plasma norepinephrine level with the degree of left ventricular dysfunction. There were no significant differences in the levels of epinephrine and dopamine in the normal subjects and the class I/II group, although there was a difference in the levels of epinephrine ($p < 0.05$) and dopamine ($p < 0.01$) in the normal groups and the class III/IV group.

This study suggests that in CHF, human platelet $alpha_2$ adrenoreceptors may serve as a marker of elevated levels of circulating norepinephrine. Changes in the platelet receptor number may be a method of monitoring the therapy of congestive failure. Identification and characterization of these receptors suggest the possibility of using $alpha_2$-agonist agents such as clonidine or alpha methyldopa to stimulate these inhibitory sites and thus decrease norepinephrine release. This may, in turn, protect the myocardium from the excessively high levels of circulating norepinephrine as has been done with beta-adrenergic blockade. Further studies in humans are needed to ascertain whether successful therapy in patients with CHF restores the receptor number to normal. These changes should be correlated in animal models of heart failure with neuronal release of norepinephrine after nerve stimulation. Such changes may prove important in developing new therapeutic strategies in the treatment of CHF.

Acknowledgment: We express appreciation to Joann Geer and Sarah Moss for their invaluable technical assistance.

Cardiovascular Effects of Breathing 95 Percent Oxygen In Children With Congenital Heart Disease

ROBERT H. BEEKMAN, MD, ALBERT P. ROCCHINI, MD, and AMNON ROSENTHAL, MD

The hemodynamic effects of breathing 95% oxygen were evaluated in 26 children with congenital heart disease. Aortic, pulmonary arterial, right atrial, and pulmonary arterial wedge pressure, aortic and pulmonary artery oxygen saturation, and blood gas, cardiac index, and heart rate were measured in room air and after each patient had breathed 95% oxygen for 10 (n = 26) and 20 (n = 5) minutes. Measurements were repeated with the patient again breathing room air for 10 (n = 11) and 20 (n = 6) minutes. After 10 minutes of 95% oxygen, arterial partial pressure of oxygen increased from 85 ± 13 to 420 ± 89 torr ($p < 0.001$). Aortic mean pressure increased from 80 ± 10 to 83 ± 10 mm Hg ($p < 0.01$), and systemic vascular resistance increased from 20 ± 7 to 26 ± 8 U ($p < 0.001$). The cardiac index decreased by 21% from 3.96 ± 0.94 to 3.12 ± 0.74 liters/min/m^2 ($p < 0.001$) and the stroke index decreased by 11% ($p < 0.001$). A 23% decrease in oxygen consumption ($p < 0.001$) was observed, and oxygen transport decreased from 763 ± 179 to 600 ± 161 ml O_2/min/m^2 ($p < 0.001$). Cardiac index, stroke index, and systemic vascular resistance did not return to normal until 20 minutes after cessation of oxygen breathing. To determine whether reflex bradycardia is responsible for these oxygen-induced hemodynamic changes, heart rate was kept constant by atrial pacing in a second group of 5 patients. In these children, significant decreases in cardiac index, stroke index, and oxygen consumption, and increases in systemic vascular resistance also occurred with 95% oxygen. Thus, in children with acyanotic congenital heart disease, hyperoxia increases aortic pressure and systemic vascular resistance and decreases cardiac index, stroke index, oxygen consumption, and oxygen transport.

The medical and surgical therapy of children with heart disease frequently includes administration of oxygen. The goal is to improve systemic oxygen delivery in patients with cyanosis, heart failure, or pulmonary edema. Previous studies have indicated, however, that oxygen itself may significantly alter cardiovascular hemodynamic function. In animals and in adults without heart disease, high inspired oxygen concentrations have been shown to increase systemic arterial pressure and systemic vascular resistance (SVR), and to decrease heart rate and cardiac index (CI).[1–6] Similar studies have not been performed in children or in patients with heart disease. The present study was therefore designed to evaluate the hemodynamic effects of oxygen administration in children with acyanotic congenital heart disease.

Methods

The study involved 31 children with congenital heart disease who were undergoing diagnostic cardiac catheterization. There were 18 males and 13 females ranging in age from 0.2 to 15.5 years (mean 5.5). Twenty patients had previously undergone surgical repair of the following congenital heart defects: ventricular septal defect (n = 10), endocardial cushion defect (n = 3), patent ductus arteriosus (n = 3), D-transposition (n = 2), tetralogy of Fallot (n = 1), and total anomalous pulmonary venous return (n = 1). The remaining patients, who not been operated on, had aortic stenosis (n = 3), cardiomyopathy (n = 3), aortic regurgitation (n = 1), mitral regurgitation (n = 1), pulmonary stenosis (n = 1), L-transposition with pulmonary stenosis (n = 1), and primary pulmonary hypertension (n = 1). No patient had an intracardiac shunt documented at cardiac catheterization although several appeared to have a small intrapulmonary right-to-left shunt. Five patients (Table I: Patients 2, 12, 14, 20, 25) had congestive heart failure requiring treatment with digoxin and diuretics. Patients 2, 24, 25 and 26 had moderate to severe pulmonary artery hypertension (mean pulmonary pressure ≥0.5 mean aortic pressure). Patients 1, 2, 5 to 7, 26 and 31 had multiple episodes of pneumonia and evidence on chest roentgenography of chronic pulmonary disease.

Before catheterization, each patient was premedicated with morphine sulfate (0.15 mg/kg) and diphenhydramine (1.0 mg/kg). After right and left heart catheterization had documented the underlying lesion, and before angiography, the study was performed. Baseline hemodynamic variables were measured with the patient breathing room air. Heart rate was determined from the electrocardiogram and averaged over a 10-second period. Pressures were measured in the aorta, right atrium, pulmonary artery, and pulmonary artery wedge position. Aortic and pulmonary artery blood was sampled for blood gas (IL 813 analyzer) and oxygen saturation (reflection oximetry) measurements. All blood gas samples were collected in cold heparinized syringes, placed in ice, and analyzed within 5 minutes. Hemoglobin concentration was measured in an IL 182 co-oximeter, and oxygen-carrying capacity was calculated by multiplying the hemoglobin concentration by 1.36. CI was measured by thermodilution technique (IL 701 thermodilution computer) and taken as the average of 3 determinations. In 5 patients, CI was also measured by dye dilution technique. Oxygen consumption (VO_2) was measured using a continuous flow-through system in room air,[7] and was also calculated from thermodilution CI and oxygen content difference according to the Fick principle in both room air and 95% oxygen: VO_2 = thermal dilution cardiac output (10 × [oxygen capacity × aortic saturation + 0.003 × aortic PO_2]) − (oxygen capacity × pulmonary artery saturation + 0.003 × pulmonary artery PO_2), where PO_2 = partial pressure of oxygen. Core temperature was measured with thermodilution thermistor situated in the main pulmonary artery.

After acquisition of baseline data, each patient was administered 95% oxygen. This was the highest inspired oxygen concentration that could be reliably administered by a hood system. Inspired oxygen concentration (F_IO_2) was determined using an Applied Electrochemistry oxygen analyzer. Measurements of heart rate, pressures, blood gases and saturations, CI, and VO_2 were made as just described after oxygen breathing for 10 minutes (n = 26) and 20 minutes (n = 5). Hemodynamic measurements were then repeated with the patient once again breathing room air for 10 minutes (n = 11) and 20 minutes (n = 6).

To evaluate the hemodynamic significance of reflex bradycardia during oxygen breathing, heart rate was kept constant by atrial pacing (rate 5 beats/min above the spontaneous sinus rate) in 5 patients. Hemodynamic measurements were made in room air and after breathing 95% oxygen for 10 minutes as described previously.

Data were evaluated for significance using the two-tailed *t* test for paired observations. All values are expessed as mean ± standard deviation.

Results

After 10 minutes of breathing 95% oxygen, mean arterial PO_2 increased from 86 ± 13 to 420 ± 89 torr ($p < 0.001$) and arterial oxygen content increased from 17.0 ± 1.9 to 18.7 ± 2.0 ml/100 ml ($p < 0.001$). There was a slight increase in these values after 20 minutes of oxygen breathing. The increase in mean arterial PO_2 to only (420 ± 89 torr) after 10 minutes of breathing 95% oxygen suggests that some degree of intrapulmonary right-to-left shunting was present in our patients. Arterial pH, PCO_2, and temperature did not change during the study.

Significant hemodynamic effects were noted after 10 minutes of oxygen breathing (Table I). Heart rate decreased from 103 ± 21 to 94 ± 22 beats/min ($p < 0.001$). Mean systemic arterial pressure increased from 80 ± 11 to 83 ± 10 mm Hg ($p < 0.01$), and mean pulmonary arterial pressure decreased from 24 ± 12 to 22 ± 11 mm Hg ($p < 0.01$). Mean right atrial pressure increased from 5 ± 2 to 6 ± 2 mm Hg ($p < 0.01$), while the small observed increase in pulmonary arterial wedge pressure from 10 ± 5 to 11 ± 5 mm Hg ($p = 0.15$) did not reach statistical significance.

CI measured by thermodilution technique was diminished in every patient after 10 minutes in 95% oxygen. Mean CI decreased by 21% from 3.96 ± 0.94 to 3.12 ± 0.74 liters/min/m^2 ($p < 0.001$). Stroke index decreased by 11% from 39.9 ± 11.1 to 35.5 ± 9.7 ml/m^2 ($p < 0.001$). In 5 patients, CI determined by dye dilution did not differ significantly from simultaneous thermodilution measurements.

Oxygen breathing resulted in a significant elevation of SVR from 20.1 ± 6.9 to 25.5 ± 7.7 U ($p < 0.001$). Pulmonary vascular resistance did not change significantly.

VO_2 was calculated from thermodilution cardiac output according to the Fick principle. In room air, this calculated VO_2 did not differ significantly from VO_2 measured by a continuous flow-through system (150 ± 26 versus 156 ± 24 ml/min/m^2, respectively). After 10 minutes of breathing 95% oxygen, VO_2 decreased by 24% ($p < 0.001$) (Table I). Oxygen transport, the product of arterial oxygen content and cardiac output, decreased as well, from 762.9 ± 179.4 to 600.2 ± 161.3 ml O_2/min/m^2 ($p < 0.001$).

After 20 minutes of oxygen breathing, no further hemodynamic changes were noted. The data in Table II indicate that hemodynamic measurements made after 20 minutes did not differ significantly from those made after 10 minutes of breathing 95% oxygen. Thus, oxygen seems to exert its major cardiovascular effects within 10 minutes. Ten minutes after cessation of oxygen breathing, however, all values had not returned to baseline (Table III). CI, stroke volume, oxygen transport, and VO_2 remained significantly depressed and SVR remained elevated ($p < 0.01$). These and all other hemodynamic parameters returned to normal after 20 minutes after oxygen breathing.

The effects of breathing 95% oxygen on the 5 patients with congestive heart failure are presented in the Figure 1. These data are highlighted since the hemodynamic effects of oxygen in such patients may be of particular clinical relevance. When compared with the 21 patients without failure, oxygen decreased CI and stroke volume and increased SVR in the 5 children with congestive failure. CI decreased from 2.95 ± 0.95 to 2.38 ± 0.79 liters/min/m^2 ($p < 0.05$), stroke index decreased from 28.1 ± 13.4 to 23.6 ± 11.1 ml/m^2 ($p < 0.05$), and SVR increased from 27.7 ± 11.8 to 34.0 ± 13.1 U ($p < 0.05$).

To evaluate the role played by reflex bradycardia during oxygen breathing, heart rate was held constant by atrial pacing in 5 patients. Hemodynamic values measured before oxygen and after breathing 95% oxygen for 10 minutes are presented in Table IV. CI and stroke index both decreased by 12% ($p < 0.05$). VO_2 also decreased from 146.2 ± 42.2 to 97.0 ± 12.0 ml/min/m^2 ($p < 0.05$). SVR increased in oxygen from 22.8 ± 5.1 to 26.4 ± 5.5 U ($p < 0.05$).

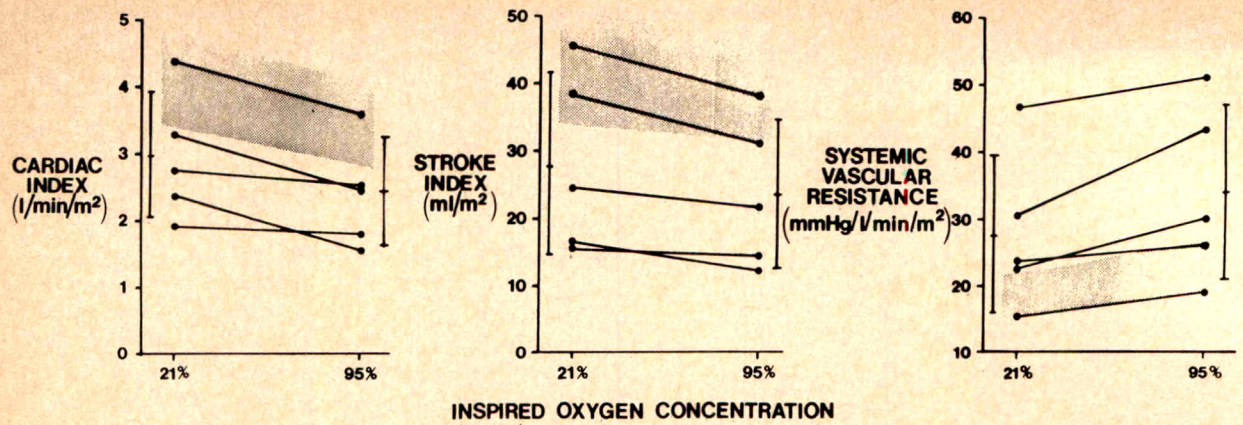

FIGURE 1. Cardiovascular effects of oxygen.

Discussion

This study documents significant hemodynamic changes induced by the breathing of 95% oxygen in children with congenital heart disease. Oxygen breathing increased SVR and arterial pressure, and decreased heart rate, CI, and stroke volume. A marked decrease in VO_2 was observed as well. These hemodynamic changes occurred in all patients regardless of cardiac diagnosis or the presence of intrapulmonary right-to-left shunting.

Several studies have documented an increase in SVR induced by hyperoxia.[1–6,8] Eggers et al[1] noted a 22% increase in 10 healthy adults breathing 100% oxygen for 20 minutes. Torbati et al,[5] studying rats exposed to high oxygen tension, concluded that the elevated SVR was due primarily to vasoconstriction in large muscle groups. This is consistent with observations, using venous occlusion plethysmography, that forearm blood flow is reduced by 18.9% in adults breathing oxygen at 2 atm pressure.[8] Hyperoxia has been shown to affect SVR by increasing precapillary sphincter tone.[9] The mechanism by which oxygen increases SVR remains unclear, however. A direct constrictor effect of oxygen on arteriolar smooth muscle and chemoreceptor-mediated reflex vasoconstriction have been postulated.[20] The observation that significant hemodynamic effects persist for 20 minutes (40 minutes in Egger et al's study[1]) despite normalization of arterial oxygen content suggests that a circulating vasoconstrictor substance may also be involved in mediating the cardiovascular response to hyperoxia.

A decrease in heart rate during oxygen breathing has also been reported by a number of investigators.[1–3,5,11,12] Daly and Bondurant[2] demonstrated an inverse linear relationship between heart rate and inspired oxygen concentration in 15 normal adults. After administration of atropine, however, heart rate did not decrease in response to high inspired oxygen concentrations. Thus, it appears that hyperoxia-induced bradycardia may be mediated by the baroreflex in response to an increase in arterial pressure.

CI decreases in response to hyperoxia.[1–6,13] Our data indicate that this is due to the combined effects of a decrease in both heart rate and stroke volume. CI decreased by 21% after 10 minutes of breathing 95% oxygen. In the 5 patients whose heart rates were kept constant by atrial pacing, CI decreased by 12%, entirely the consequence of a diminished stroke volume. This 12% decrease in stroke volume was almost identical in magnitude to that observed in the 26 nonpaced patients.

Abbreviations as in Table I.

Thus, the decrease in CI during oxygen breathing is due to a decrease in stroke volume as well as heart rate. In contrast, Daly and Bondurant[2] failed to demonstrate a statistically significant decrease in stroke volume in 6 patients during oxygen breathing when reflex bradycardia was abolished by atropine administration. Their data show, however, that stroke volume did decrease in 4 subjects and was unchanged in 2.

The oxygen-induced decrease in stroke volume may be due to multiple factors. First, it may reflect an increased SVR and left ventricular afterload. This factor may be of particular significance in children with heart disease. Second, the decrease in stroke volume may relate to myocardial depression by hyperoxia. Several studies have documented diminished ventricular function in animals exposed to high oxygen concentrations.[10–16] Kioschos et al,[15] for example, found a 14% decrease in the first derivative of left ventricular pressure in dogs during hyperbaric oxygenation at 3.6 atm for 15 minutes. Finally, hyperoxia has been shown to decrease coronary artery blood flow,[14,17] which may further compromise myocardial function.

The hemodynamic response to hyperoxia may be of particular clinical relevance in children with congestive heart failure and already compromised ventricular performance. Figure 1 illustrates some of the hemodynamic changes induced by breathing 95% oxygen for 10 minutes in 5 children with heart failure. In room air, these children already had a mean CI and stroke index well below, and a mean SVR well above the group as a whole. Nevertheless, oxygen administration caused a further 19% decrease in CI and 16% decrease in stroke index. SVR resistance increased by 23% from 27.7 to 34 units. These potentially adverse hemodynamic effects were noted in each child after 10 minutes of oxygen administration.

In the present study, VO_2 decreased by 25% after 10 minutes in 95% oxygen. A similar marked decrease in VO_2 has been reported during hyperbaric oxygenation.[13] The mechanisms involved are unknown but one can speculate that peripheral vasoconstriction and decreased cardiac output may cause underperfusion of metabolizing tissues. In fact, the present data have shown that oxygen transport, the volume of oxygen delivered to the tissues each minute, is depressed by hyperoxia. Oxygen in high concentration may also directly inhibit oxidative metabolism. In rabbits exposed to oxygen at 3 atm a marked lactic acidosis develops, supporting the concept that aerobic metabolism is inhibited by hyperoxia.[18]

The present study has a number of potential clinical implications. First, at cardiac catheterization it is common to assess the hemodynamic response to oxygen breathing of patients with intracardiac shunts or pulmonary vascular obstructive disease. Our findings suggest that pulmonary blood flow may be overestimated and pulmonary resistance underestimated if one assumes that oxygen consumption in oxygen is the same as that measured in room air. Second, the medical and surgical therapy of children with acyanotic heart disease often includes administration of oxygen in the range of inspired oxygen concentration of 30 to 50%. Thus, further investigations are warranted to determine if similar adverse hemodynamic changes occur when these therapeutic concentrations of oxygen are given.

Altered Baroreceptor Function in Children With Systolic Hypertension After Coarctation Repair

ROBERT H. BEEKMAN, MD, BARRY P. KATZ, MPH,
CATHERINE MOOREHEAD-STEFFENS, BS, and ALBERT P. ROCCHINI, MD

To determine whether altered baroreceptor function may contribute to systemic hypertension after coarctation of the aorta (C of A) repair, baroreceptor function was evaluated in 6 children with repaired C of A mild arm systolic hypertension. Data were compared with those from 7 normotensive control children with hemodynamically mild heart disease. Age at C of A repair averaged 9.9 ± 3.1 years (mean ± standard deviation [SD]). Arm systolic pressure was 143.8 ± 2.9 mm Hg in the C of A repair group, compared with 118.3 ± 9.9 for control subjects ($p < 0.001$). At catheterization, steady-state sigmoidal baroreceptor function curves relating mean arterial pressure to R-R interval were derived by increasing and decreasing mean arterial pressure with small injections of phenylephrine and nitroprusside. Compared with control subjects, the baroreceptor function curves of children with repaired C of A (1) are reset about a higher baseline mean arterial pressure (108.8 ± 6.6 versus 90.3 ± 8.6 mm Hg, $p < 0.01$), (2) have a decreased slope (7.9 ± 3.7 versus 17.4 ± 3.6 ms/mm Hg, $p < 0.001$), and (3) have a diminished R-R interval range (246.7 ± 81.5 versus 535.7 ± 97.2 ms, $p < 0.001$). Thus, in children with hypertension after C of A repair, the baroreflex is reset to an elevated mean arterial pressure level and has a diminished sensitivity to changes in arterial pressure.

Arm hypertension, at rest or during dynamic exercise, occurs frequently after repair of coarctation of the aorta (C of A).[1–5] In some patients, hypertension is clearly related to a residual or recurrent C of A.[6] In others, however, those with little or no residual resting C of A gradient, the cause of postoperative hypertension is less clear. The baroreflex is intimately involved in blood pressure regulation, but its function in patients with repaired C of A has not been evaluated. Nevertheless, studies in dogs with experimental C of A[7,8] have documented baroreflex alterations similar to those described in adults with chronic essential hypertension.[9–11] The purpose of this study is to evaluate baroreceptor function in children with repaired C of A who have mild arm hypertension.

Methods

Six children, 5 boys and 1 girl, with good surgical repair of C of A (resting peak systolic gradient of <25 mm Hg) and mild resting arm systolic hypertension (>140 mm Hg) served as subjects of this investigation. A group of 7 normotensive children with hemodynamically mild heart disease served as control subjects. Pertinent clinical and hemodynamic data are presented in Table I. The children with repaired C of A ranged in age from 13.8 to 19.0 years, averaging 16.8 ± 2.0 years (mean ± SD). The control children averaged 15.4 ± 4 years of age, which is not significantly different from that in the C of A repair group. The 6 children with repaired C of A had undergone repair of a discrete thoracic C of A at an average age of 9.9 ± 3.1 years (range 6.8 to 13.8). Before C of A repair, all children had resting arm hypertension (defined as systolic pressure at or above the 95th percentile for age and sex) averaging 146.8 ± 16.2 mm Hg. C of A repair was performed by end-to-end anastomosis in 4 children (Patients 3 to 6) and by patch aortoplasty in 2 (Patients 1 and 2). Immediately after surgical repair, 5 children (Patients 1, 2, 3, 5, and 6) had paradoxical hypertension requiring vigorous antihypertensive therapy for 2 to 3 days. The interval from repair to the present study averaged 6.9 ± 3.7 years. At the time of this study, no patient was receiving antihypertensive medication or digoxin. There were no associated hemodynamic lesions of significance. One patient (Patient 4) had also undergone repair of a ventricular septal defect with excellent

AS = aortic stenosis; AsAo = ascending aorta; C of A = coarctation of aorta; DescAo = descending aorta; dias = diastolic; HR = heart rate; NS = not significant at $p < 0.05$; PS = pulmonic stenosis; Rt = right; SD = standard deviation; syst = systolic; TOF = tetralogy of Fallot; VSD = ventricular septal defect.

results, and another (Patient 6) had trivial mitral insufficiency. No patient had aortic insufficiency or aberrant right subclavian artery.

Outpatient blood pressure was measured by auscultation in the right arm and by the use of a Doppler flow probe over the posterior tibial artery. Blood pressure cuffs of appropriate size, covering at least two thirds of the limb, were used on the right upper arm and calf. All reported blood pressure values are the average of at least 3 measurements.

Dynamic exercise testing was performed on a motorized treadmill according to the Bruce protocol.[12] All children exercised to physical exhaustion defined as inability to exercise further despite vigorous encouragement from the staff to do so. Leads II, aVF, and V_5 were recorded throughout the exercise study. Blood pressure was measured by auscultation in the right arm and by the use of a Doppler flow probe over the posterior tibial artery. Blood pressure cuffs of appropriate size, covering at least two thirds of the limb, were used on the right upper arm and calf. Simultaneous supine arm and leg blood pressure measurements were made at rest (reported values are the average of at least 3 measurements) and within 30 seconds after the conclusion of exercise.

After obtaining informed consent, all patients underwent cardiac catheterization to evaluate their coarctation repair site and to determine a possible explanation for their resting and exercise hypertension.

During diagnostic cardiac catheterization, resting baroreceptor function was evaluated in each patient before angiography. All patients received light sedation with morphine sulfate (0.1 mg/kg, maximum 5 mg) and diphenhydramine (1 mg/kg, maximum 50 mg). The R-R interval was measured directly from lead II of the electrocardiogram, recorded at a paper speed of 100 mm/s. Arterial pressure was recorded from a catheter situated in the aortic arch proximal to the site of C of A repair. Mean arterial pressure (MAP) was determined by electronic damping and was recorded, together with phasic arterial pressure, continuously throughout the study. Incremental changes in MAP were produced by injection (over 10 to 15 seconds) into the inferior vena cava of small doses of phenylephrine (50 to 150 μg) and nitroprusside (25 to 50 μg). Each drug was diluted in 0.9% sodium chloride and the total volume of each injection never exceeded 4 ml. In each subject, 3 or 4 doses each of phenylephrine and nitroprusside were administered to produce small (10%) to moderate (25%) increases and decreases in MAP. Three- to 5-minute intervals were taken between each drug injection to allow MAP and R-R interval to return to baseline levels. After each drug injection, MAP and R-R interval increased or decreased within

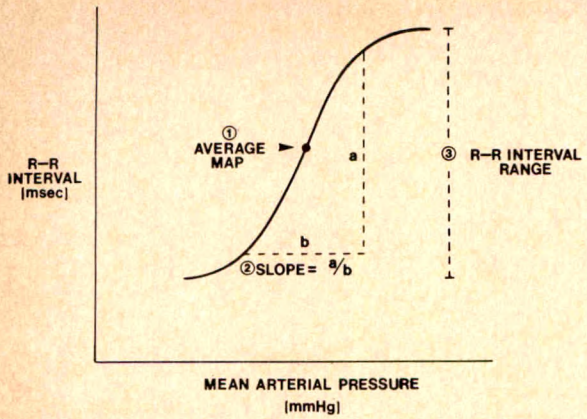

FIGURE 1. Idealized baroreceptor function curve. The curve is characterized by 3 parameters: (1) average baseline mean arterial pressure (MAP); (2) slope (a/b); and (3) R-R interval range.

15 seconds to a new plateau level which was sustained for 10 to 20 seconds. MAP was measured at baseline before, and at the plateau after each injection. The R-R interval was also measured at each baseline and plateau and the values reported represent the average of 3 consecutive R-R interval measurements. The range of MAP over which baroreceptor function was studied was comparable in the C of A repair and control group averages of 42.2 ± 2.7 mm Hg and 44.1 ± 2.9 mm Hg, respectively ($p = 0.61$).

Steady-state baroreceptor function curves were then constructed for each child by relating each R-R interval to its corresponding MAP value. Sigmoidal curves were constructed using the cumulative standard normal distribution function (ϕ)*. This sigmoidal function was utilized since previous studies have shown that the baroreceptor function curve is sigmoidal in nature.[11] Each patient's baroreceptor function curve was defined by the following equation: $RR = A + B\,\phi(MAP - \overline{MAP})/SD_i$, where i represents phenylephrine or nitroprusside, RR represents each R-R interval, and MAP each corresponding MAP value. $\overline{MAP}$ is the average baseline MAP for the patient. SD represents the standard deviation for each patient of the MAP values measured after drug injections either with phenylephrine or nitroprusside. Since the relationship between R-R interval and mean arterial pressure has been shown to be characterized by an asymmetric sigmoid curve,[11] 2 different standard deviations were used in constructing the upper and lower portions of the curve, respectively—one for the MAP values greater than $\overline{MAP}$ (that is, after phenylephrine) and another for the $\overline{MAP}$ values less than MAP (such as after nitroprusside). This procedure permitted each curve to be asymmetrical if warranted by the data. A separate A and B were determined for each subject using least-squares linear regression, since data within subjects were correlated.

Each patient's baroreceptor function curve was characterized by 3 parameters: (1) average baseline MAP, (2) slope, and (3) R-R interval range. Figure 1 depicts an idealized baroreceptor curve with these 3 parameters indicated. Average baseline MAP ($\overline{MAP}$) is the average of all MAP values at baseline before each drug injection, and represents the set-point pressure about which the baroreflex operates. The slope of a baroreceptor function curve is an index of baroreflex sensitivity to changes in arterial pressure. In this study the reported slope is the average slope of the linear portion of the curve over a pressure range defined as $\overline{MAP} \pm 1$ SD (standard deviation for each patient of all the MAP values measured after drug injections). For example, in Figure 1 the slope is a/b, where b represents $\overline{MAP} \pm 1$ SD. The R-R interval range is the difference between the R-R interval at the upper and lower plateaus of the baroreceptor function curves. This represents the R-R range over which the baroreflex operates.

Descending aortic angiograms were obtained on all 6 C of A patients. The descending thoracic aorta at the C of A repair site and at the level of the diaphragm were measured using calibrated grids. In the 7 control patients, the descending thoracic aorta was measured from either the levophase of a right ventricular angiogram or from a left ventricular angiogram.

Statistical significance was assessed using Student's t test. Group values are reported as mean ± standard deviation.

Results

Arm systolic pressure at rest averaged 143.8 ± 2.9 mm Hg for the 6 children with repaired C of A (Table I). This ranks in the 90th percentile for systolic pressure according to the National Heart, Lung, and Blood Institute's blood pressure charts for children.[13] Resting systolic pressure was significantly lower in the control group, averaging 118.3 ± 9.9 mm Hg ($p < 0.05$). Resting diastolic pressure was normal in both groups, averaging 74.5 ± 9.4 mm Hg and 73.7 ± 6.2 mm Hg in the C of A repair and control groups, respectively. The C of A pressure gradient at rest averaged 7.8 ± 10.6 mm Hg in the 6 children with repaired C of A. There was no significant difference between study and control patients with regard to resting heart rate. All children with repaired C of A had an abnormal blood pressure elevation in response to treadmill exercise (Table I). Upper extremity systolic pressure, measured immediately after exercise, averaged 223.3 ± 13.6 mm Hg in the coarctation repair group, compared with 146.6 ± 12.1 mm Hg for the control group ($p < 0.001$). There was no overlap of postexercise systolic pressure between the 2 groups. The coarctation pressure gradient increased to 75.2 ± 33.2 mm Hg immediately after exercise. Arm diastolic pressure immediately after exercise was not significantly different in the coarctation repair and control groups, averaging 73.5 ± 15.2 mm Hg and 66.6 ± 17.8 mm Hg, respectively. Maximal heart rate attained at peak exercise was also similar in the 2 groups. At cardiac catheterization, all children appeared to have a good hemodynamic repair of C of A, with peak systolic gradients from ascending to descending aorta ranging from 0 to 20 mm Hg (mean 8.5 ± 7.3 mm Hg) (Table II). In all 6 patients, aortograms demonstrated a mild indentation of the descending aorta at the site of coarctation repair. However, in no patient was this residual narrowing <70% of the size of the descending aorta at the level of the diaphragm (Table II).

Baroreceptor function, as defined by the steady-state relationship between mean arterial pressure and R-R interval, was significantly different in the children with repaired C of A compared with control children. Figure 2 illustrates representative baroreceptor function curves of a child with repaired C of A and a control child. The

data describe sigmoidal curves with well-defined slopes in the mid-portion of the curves and clear upper and lower plateaus. Table III lists the baroreceptor function curve characteristics for the 2 groups of children. The average baseline mean arterial pressure ($\overline{MAP}$) was 108.8 ± 6.6 mm Hg for the repaired C of A group compared with 90.4 ± 8.6 mm Hg for the control group ($p < 0.01$). Thus, the baroreflex has been reset to operate at high arterial pressure levels in the children with repaired C of A. The baroreceptor function curves of the children with repaired C of A have diminished slopes compared with control curves. In these children, the slope averages 7.9 ± 3.7 ms/mm Hg, compared with 17.4 ± 5.1 ms/mm Hg in the control group ($p < 0.001$), a 55% difference. This indicates diminished baroreflex sensitivity to changes in arterial pressure in the children with repaired C of A. Finally, the R-R interval range averages 246.7 ± 81.5 ms in the C of A repair group compared with 535.7 ± 97.2 ms in the control group ($p < 0.001$). Figure 3 illustrates the composite baroreceptor

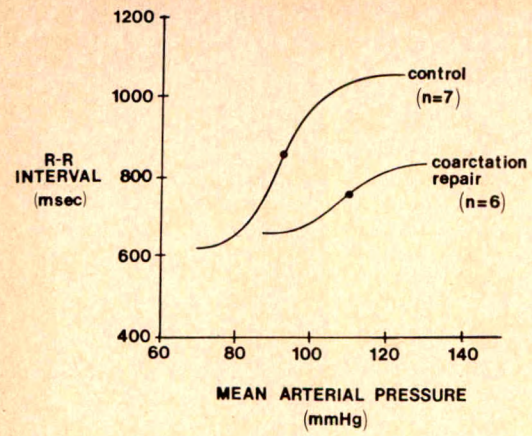

FIGURE 3. Composite baroreceptor curves of children with repaired coarctation and control children. The curves clearly differ in regard to average baseline MAP, slope, and R-R interval range.

function curves of the 6 children with repaired C of A and the 7 control children. These curves were constructed with the standard formula using averaged MAP, A, B, and SD (square root of averaged individual variances) values for the 2 groups. The two composite baroreceptor curves are clearly different. The C of A repair curve has been reset to a higher average baseline MAP and has a diminished slope compared with the control curve. The decrease in R-R interval range of the C of A repair curve is shown to be due to a lowering of the upper R-R interval plateau, indicating a diminished bradycardiac response to arterial pressure elevation.

Baseline arterial pulse pressure was higher in the children with repaired C of A than in the control children, averaging 58.6 ± 8.4 mm Hg and 40.4 ± 4.2 mm Hg, respectively ($p < 0.05$). After injection of phenylephrine or nitroprusside, however, the changes in pulse pressure were not significantly different between groups. The baroreceptor characteristics discussed above are not corrected for baseline pulse pressure differences. An adjustment for differences in pulse pressure would further increase the discrepancy in baroreceptor function between the 2 groups, since baroreflex sensitivity is known to be enhanced by increased pulse pressure.[14]

Discussion

The present study has documented altered baroreceptor function in a group of children with repaired C of A who have mild arm systolic hypertension. In these children the baroreflex is reset to operate at higher arterial pressure levels and has a reduced sensitivity to changes in arterial pressure compared with control children. The diminished baroreceptor sensitivity (slope) was marked, averaging only 45% of the control value. In addition, the baroreceptor curve of the C of A repair group had a reduced R-R interval plateau, due almost entirely to a decrease in the upper R-R interval plateau. The level of the upper R-R interval plateau is dependent upon the degree of vagal efferent excitation and cardiac sympathetic inhibition, while the lower R-R interval plateau is determined by the degree of sympathetic excitation and vagal inhibition. We do not know which cardiac effector mechanism is altered in the children with repaired C of A but, based on studies of hypertensive adults,[11] the reduced upper R-R interval plateau seems more likely due to impaired vagal excitation than to impaired sympathetic inhibition.

The findings of the present study are similar to those of previous studies reporting altered baroreceptor function in adults with chronic essential hypertension.[9–11] Korner et al,[11] using a technique similar to ours to characterize steady-state baroreceptor function, also showed resetting, reduced baroreflex sensitivity, and a diminished R-R interval range in adults with chronic hypertension. In Korner's study the baroreceptor curve slopes of adults older than 30 years with severe resting hypertension (average MAP 151 mm Hg) averaged 11 ms/mm Hg compared with 21 ms/mm Hg for age-matched control subjects. These findings are quantitatively very similar to those of the present study. It is, however, important to note that although the technique of measuring heart rate response to injections of pressor and depressor drugs free of cardiac action is the most widely used test of baroreflex function in human subjects, it has the limitation of being unable to directly measure the baroreflex control of the peripheral circulation. Despite this, with the exception of denervation of either the carotid sinus or aortic arch baroreceptors,[14] most studies in both man[15] and animals[14,16,17] have demonstrated that with intact afferents there is a positive correlation between the heart rate and the arterial pressure responses to a baroreceptor manipulation. Thus, although we have only documented an abnormal heart rate response to baroreceptor stimulation in our children after C of A repair, we feel that it is likely that an abnormality of baroreceptor regulation of vascular resistance is also present.

Baroreceptor function has not previously been evaluated in children or adults with C of A. Two previous studies have, however, demonstrated altered baroreceptor function in dogs with experimental coarctation. Bonchek et al[7] reported resetting of the baroreflex to a higher pressure level, but normal reflex sensitivity, in 10 Labrador puppies with surgically created C of A. More recently, Igler et al[8] described both resetting and diminished baroreflex sensitivity in dogs with C of A studied under nonpulsatile flow conditions. Baroreceptor function was found to be normal after surgical repair of the experimental C of A.

The cause of altered baroreceptor function in hypertension has not been clearly elucidated. Although either the afferent or efferent limb of the reflex may be involved, most investigators have suspected that the changes reside in the afferent limb. Support for this view is found in animal studies, using single or multifiber preparations from the aortic and carotid sinus nerves, which have demonstrated an elevated threshold pressure (the pressure at which distinct nerve discharge first begins), an elevated saturation pressure (the pressure at which nerve firing no longer increases with increased pressure), and a decreased sensitivity (slope

of the stimulus-response curve over its linear range).[8,18,19] Such diminished baroreceptor responsiveness to elevated arterial pressure may involve 1 or more mechanisms. First, diminished baroreceptor function in hypertension may involve dysfunction of the afferent neuronal baroreceptor fibers themselves. Generalized destruction or inactivation of these receptor fibers could, in theory, depress baroreflex sensitivity. Angell-James[19] has presented histologic evidence of baroreceptor degeneration in the aortic arch of hypertensive rabbits. Similar findings in hypertensive persons have also been reported.[20] Second (and a more likely mechanism), with chronic hypertension, medial hypertrophy, elastic fiber degeneration, atherosclerosis, and changes in vessel sodium and water content may develop. These changes in the arterial wall may all act to diminish arterial wall compliance and thereby depress the baroreflex.[21] In addition to the effects of chronic hypertension, morphologic arterial wall abnormalities may occur in patients with coarctation which may further decrease vessel compliance.[22–24] Specifically, Sehested et al[24] have demonstrated, both by in vitro stimulation of aortic tissue from patients with C of A and by morphologic analysis, that the precoarctation aortic wall is more rigid and contains significantly more collagen and less smooth muscle than the postcoarctational wall. They speculated[24] that this reduced distensibility may influence baroreceptors in the upper vascular bed in such a way as to tolerate a higher pressure.

The findings of the present study suggest but do not prove that there may be a relationship between the observed abnormality in baroreceptor function and the presence of both resting and exercise hypertension in children with repaired C of A. There is no unanimity in the literature with regard to either the relationship between diminished baroreflex gain and hypertension[25,26] or the ability of the baroreflexes to modify the cardiovascular response to exercise.[27–30] Floras et al[27] demonstrated that adults with abnormal baroreflexes respond to a standard exercise test with a greater increase in blood pressure than that observed in adults with normal baroreflexes. Although altered baroreceptor function may contribute to both the maintenance of resting hypertension and the development of exercise hypertension after successful repair of C of A, we feel that it is not the major cause of the hypertension. Probably more important other causes include the magnitude[24] and duration[1] of preoperative hypertension, the mild residual narrowing of the descending thoracic aorta that is usually present after C of A repair,[5] and the possible decreased distensibility of the ascending aortic wall.[24] Studies of the baroreceptor function in children with repaired C of A who have normal resting and exercise blood pressure would help to clarify these relationships.

Two-Dimensional Echocardiographic Assessment of Caval and Pulmonary Venous Pathways After the Senning Operation

ALVIN J. CHIN, MD, STEPHEN P. SANDERS, MD, ROBERTA G. WILLIAMS, MD, PETER LANG, MD, WILLIAM I. NORWOOD, MD, PhD, and ALDO R. CASTANEDA, MD, PhD

This study reports the 2-dimensional echocardiographic appearance of the caval and pulmonary venous pathways after the Senning procedure in 28 patients and establishes normal values for the caval and pulmonary venous pathway dimensions. Eighteen patients had no caval or pulmonary venous obstruction or tricuspid regurgitation at catheterization; 2 had isolated superior vena caval obstruction, 3 had isolated pulmonary venous obstruction, 4 patients had severe tricuspid regurgitation, and 1 had a large residual ventricular septal defect. The caval and pulmonary venous pathways were imaged in modified 4-chamber and transverse views, and the narrowest dimension of each pathway in each view was measured by 2 independent observers. Dimension measurements were then normalized to the cube root of body surface area. Caval and pulmonary venous pathway "dimension products" were obtained by multiplying the normalized dimension in the 4-chamber view by the normalized dimension in the transverse view.

All patients with catheterization-proven caval or pulmonary venous obstruction or tricuspid regurgitation had caval or pulmonary venous pathway dimension products outside the normal range, defined by our measurements in the 18 patients with no caval or pulmonary venous obstruction or tricuspid regurgitation. Thus, 2-dimensional echocardiography can provide both quantitative and qualitative information about the caval and pulmonary venous pathways after the Senning procedure.

Obstruction of either pulmonary or systemic venous return is the most common hemodynamic complication of the Senning procedure for d-transposition of the great arteries with intact ventricular septum.[1–4] When ventricular septal defect closure is combined with the Senning procedure as treatment for d-transposition of the great arteries with ventricular septal defect or for double-outlet right ventricle with subpulmonary ventricular septal defect and no subpulmonary stenosis, tricuspid regurgitation (TR) is an additional possible hemodynamic complication. A noninvasive technique[5] for evaluating the venous pathways would be desirable not only as a means of diagnosing obstruction or atrioventricular valve regurgitation, but also as a safe, convenient method for obtaining longitudinal data on the dimensions of the atrial compartments after the Senning procedure. To date, only a few centers have reported late postoperative catheterization data on survivors of the Senning procedure.[2–4,6] The prevalence of late development of systemic or pulmonary venous obstruction or TR will influence whether an atrial baffle operation such as the Senning procedure remains a viable surgical choice for transposition of the great arteries. Concerns about the development of supraventricular dysrhythmias,[7] atrial dysfunction,[8] and right ventricular dysfunction have already led some surgeons to abandon atrial baffle operations in favor of the arterial switch.[9,10] This study reports the 2-dimensional

(2-D) echocardiographic appearance of the caval and pulmonary venous pathways after the Senning procedure and establishes normal values for caval and pulmonary venous pathway dimensions.

Methods

Between July 1, 1979, and March 30, 1982, 28 patients (aged 3 weeks to 4 4/12 years, median 14 months) with d-transposition of the great arteries and intact ventricular septum (20),

TABLE II Cardiac Catheterization Data in 10 Patients With Hemodynamic Abnormalities After the Senning Procedure

Patient	Age (mo) at Cath	Time After Op (mo)	Preoperative Diagnosis	Catheterization Data: SVC-Neo RA Grad (mm Hg)	IVC-Neo RA	PCWa-RVEDP	TR	Other
Group II: Isolated SVC Obstruction								
19	1	2 Weeks	dTGA	10	1	2*	0	0
20	3	3 Days	dTGA	7	4	2	—	0
Group III: Isolated Pulmonary Venous Obstruction								
21	14	7	dTGA	1	NA	7	0	0
22	20	13	dTGA	0	0	7†	0	0
23	6	6	dTGA	4	1	20‡	—	0
Group IV: Severe Tricuspid Regurgitation								
24	4	1	dTGA, AVC-type VSD	1	2	3*	Severe	L→R vent shunt (Qp/Qs = 1.7)
25	12	2	DORV, PAB + coarc repair	1	1	0†	Severe	L→R atrial shunt (Qp/Qs = 1.9)
26	39	34	dTGA, AVC-type VSD	1	0	3	Severe	L→R vent shunt (Qp/Qs = 2.4)
27	7	4	dTGA, memb +2 musc VSD	7	4	1	Severe	L→R atrial shunt (Qp/Qs = 1.8)
Group V: Large Residual Ventricular Septal Defect								
28	7	3 Weeks	DORV, subpulm VSD, OMV	3	2	0	mild	L→R vent shunt (Qp/Qs = 2.8) (PPA = 3/4 systemic)

* Measured pulmonary capillary wedge mean pressure to right ventricular end-diastolic pressure.
† Measured proximal neo-left atrium to distal neo-left atrium.
‡ Measured pulmonary capillary wedge mean pressure to distal neo-left atrium.
AVC-type = atrioventricular canal type; coarc = coarctation; DORV = double-outlet right ventricle; dTGA = d-transposition of the great arteries; L→R = left to right; Memb = membranous; Musc = muscular; OMV = overriding mitral valve; PAB + coarc = pulmonary trunk banding and coarctation repair; subpulm = subpulmonary; vent = ventricular; other abbreviations as in Table I.

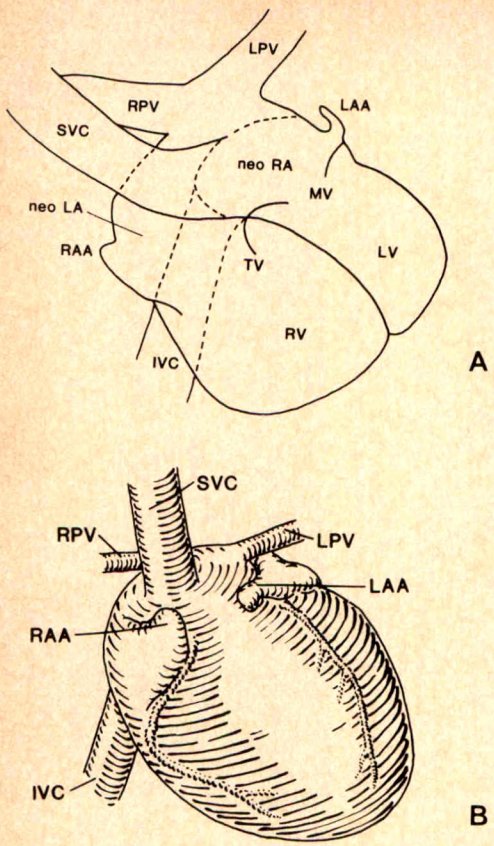

FIGURE 1. A, diagram of atrial and ventricular anatomy after the Senning procedure. The superior vena cava (SVC) and inferior vena cava (IVC) have been moved leftward to drain into the neo-right atrium (neo RA). Around the neo RA "wraps" the hemitorus-shaped neo-left atrium (neo LA), into which the pulmonary veins drain. The morphologic left atrial appendage (LAA) is part of the neo RA and the morphologic right atrial appendage is part of the neo LA. **B,** external view of atrial and ventricular anatomy after the Senning procedure. The great arteries are not depicted so that the relationship between the venous structures may be seen more easily. The neo LA "interlocks" with a second hemitorus, formed by the SVC, IVC, and neo RA. LPV = left pulmonary vein; LV = left ventricle; MV = mitral valve; RPV = right pulmonary vein; RV = right ventricle; TV = tricuspid valve.

d-transposition and ventricular septal defect (6), or double-outlet right ventricle with subpulmonary ventricular septal defect (2) were enrolled in this study. All had been repaired using the Senning procedure and, when necessary, transatrial closure of a ventricular septal defect. In addition, all patients had undergone subxiphoid 2-D echocardiography and cardiac catheterization postoperatively; subxiphoid echocardiographic examinations were performed within 2 weeks of the cardiac catheterization. Cardiac catheterization was performed 2 days to 34 months (median 12 months) after repair.

Eighteen patients had no significant superior vena caval, inferior vena caval, or pulmonary venous obstruction or TR at cardiac catheterization (Group I). Table I summarizes the hemodynamic data of this group. (For the sake of brevity, Group I is referred to as "normal" in the remainder of this report.)

Two patients had isolated superior vena caval obstruction, defined as a pressure gradient between superior vena cava and neo-right atrium of >5 mm Hg at cardiac catheterization (Group II). Three patients had isolated pulmonary venous obstruction, that is, a pressure gradient of >5 mm Hg between either the a wave or the mean of the pulmonary capillary wedge pressure and the simultaneous right ventricular end-diastolic pressure (Group III). Four patients had severe TR demonstrated by right ventricular angiography at cardiac catheterization (Group IV). One of these 4 patients had superior vena caval and mild inferior vena caval obstruction (inferior vena caval–neo-right atrial gradient 4 mm Hg) in addition to severe TR. Finally, 1 patient had a large residual ventricular septal defect with minimal TR (Group V). The hemodynamic data of Groups II through V are summarized in Table II.

Technique: Subxiphoid 2-D echocardiography was performed with a Picker Echoview 80 CI system, using either a 5 mHz short focus (active element diameter 13 mm), 5 mHz long focus (active element diameter 19 mm), or 3.5 mHz long focus (active element diameter 19 mm) crystal.

The systemic and pulmonary venous pathways after the Senning operation resemble 2 interlocking hemi-tori (Fig. 1). Subxiphoid 2-D echocardiography was begun by imaging the heart in the 4-chamber view. Although we centered our transducer and enlarged the image so that only 2 of the 4 chambers were displayed on the screen (namely the 2 atria), this view will still be referred to as the 4-chamber view in the remainder of this report since it represents the same echocardiographic *plane* as a "classic" 4-chamber view. The pulmonary venous atrium (neo-left atrium) appears as a "horseshoe" encircling the systemic venous atrium (neo-right atrium) (Fig. 2). From this view, slight clockwise rotation (10 to 15°) of the transducer displayed the superior vena caval pathway and its junction with the neo-right atrium (Fig. 3). Slight counterclockwise rotation (10 to 15°) from the 4-chamber view displayed the inferior vena caval pathway and its junction with the neo-right atrium (Fig. 4).

The caval pathways and their junction with the neo-right atrium were also easily recognized in a transverse view (Fig. 5). By angling the transducer further to the patient's right from this transverse plane until the caval–neo-right atrial junctions disappeared from view, we were able to image the entire neo-left atrium (Fig. 6).

Measurements: The borders of the caval and pulmonary venous pathways were traced by 2 independent observers on acetate overlays at end-diastole (q wave on the electrocardiogram) for 3 cardiac cycles. From these tracings, the narrowest diameter of the caval and pulmonary venous pathways in each of the 2 views (4-chamber and transverse) were measured. These narrowest diameter measurements are referred to as dimensions in the remainder of this report.

The dimension measurements were normalized to the cube root of body surface area.[11] For each venous pathway, the normalized 4-chamber dimension was multiplied by the normalized transverse dimension to yield a dimension product. In 1 patient only, the inferior vena cava was not imaged in the 4-chamber view. In all other patients, all the venous pathways were imaged in both the 4-chamber and transverse views.

In addition, we qualitatively evaluated systolic expansion of the neo-left atrium as a potential indicator of TR.

Results

The narrowest diameter of the pulmonary venous pathway was uniformly situated at the point where the systemic venous pathway impinges upon the anastomosis between the right pulmonary veins and the old right atrial free wall. This point will be referred to as the isthmus of the neo-left atrium (Fig. 2 and 6).

Group I (normal): The normalized dimensions of the superior vena caval pathway were 10.8 ± 1.2 mm (mean ± standard deviation) (4-chamber view) and 11.2

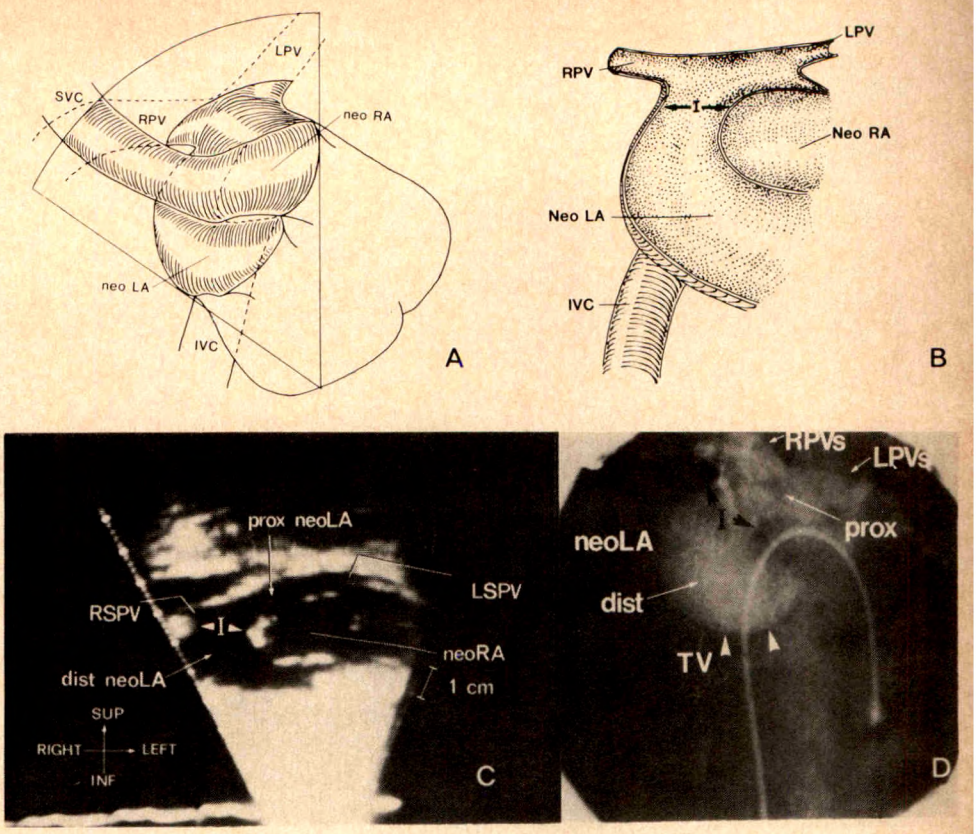

FIGURE 2. A, diagram of the echocardiographic plane used to obtain the subxiphoid 4-chamber view. The sector is directed at only the 2 atria. The shaded structures are on the near side of the sector plane. **B,** diagram of the heart as it would appear if it were "cut open" along the sector plane. The narrowest diameter of the neo-left atrium (neo LA) occurs adjacent to the entrance of the right pulmonary veins. This is termed the isthmus (I) of the neo-left atrium. **C,** 2-D echocardiogram of Patient 9, 4-chamber view. The neo-left atrium consists of a proximal (prox) portion, into which the pulmonary veins drain, and a distal (dist) portion above the tricuspid valve. The isthmus (I) connects the 2 portions of the neo-left atrium. **D,** levophase angiocardiogram of Patient 11, hepatoclavicular view. The catheter, situated in the left ventricular apex, has traversed the inferior vena cava (IVC) and neo-right atrium (neo RA). The hemitoroidal shape of the neo-left atrium, which encircles the neo-right atrium, is easily seen. LSPV = left superior pulmonary vein; RSPV = right superior pulmonary vein. Other abbreviations as in Figure 1.

± 2.3 mm (transverse view). The superior vena caval dimension product ranged from 82 to 194 mm^2. The normalized dimensions of the inferior vena caval pathway were 12.7 ± 3.1 mm (4-chamber view) and 11.7 ± 2.6 mm (transverse view). The inferior vena caval dimension product ranged from 74 to 252 mm.^{2} The normalized dimensions of the isthmus of the neo-left atrium were 18.4 ± 3.4 mm (4-chamber view) and 19.6 ± 3.2 mm (transverse view). The pulmonary venous dimension product ranged between 200 and 516 mm.^{2}

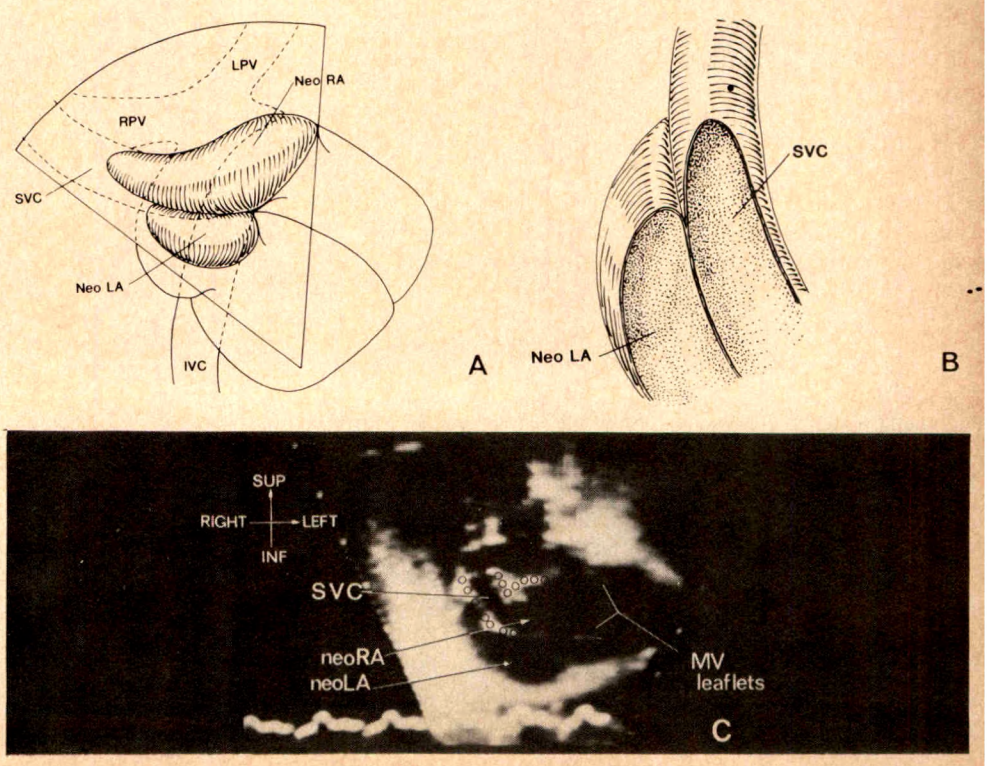

FIGURE 3. A, diagram of the modified 4-chamber echocardiographic plane used to image the superior vena caval–neo-right atrial junction. The shaded structures are on the near side of the sector plane. **B,** diagram of the heart as it would appear if it were "cut open" along the sector plane. **C,** 2-D echocardiogram of the superior vena caval pathway of Patient 18. Abbreviations as in Figure 1.

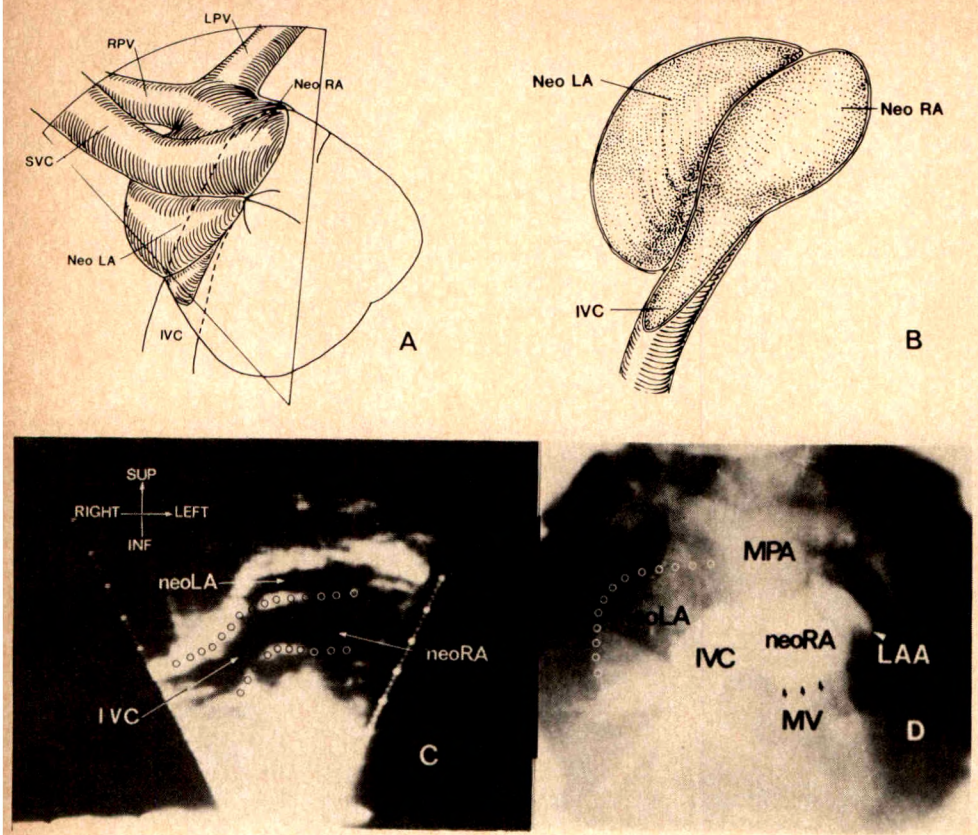

FIGURE 4. A, diagram of the modified 4-chamber echocardiographic plane used to image the inferior vena caval–neo-right atrium junction. The shaded structures are on the near side of the sector plane. **B,** diagram of the heart as it would appear if it were "cut open" along the sector plane. **C,** 2-D echocardiogram of the inferior vena caval pathway of Patient 9. **D,** angiocardiogram of the inferior vena cava and neo-right atrium of Patient 12, hepatoclavicular view. The morphologic left atrial appendage (LAA) is part of the neo-right atrium. The **open circles** outline the border of the neo-left atrium. MPA = main pulmonary artery; other abbreviations as in Figure 1.

Group II (isolated superior vena caval obstruction): The dimension of the superior vena caval pathway in the 4-chamber view for 1 of the 2 Group II patients was clearly outside the normal range; however, the 4-chamber superior vena caval dimension of the other patient was at the lower limits of normal (Fig. 7A). In the transverse view, the superior vena caval pathway dimension for both Group II patients was slightly below normal (Fig. 7B). The superior vena caval dimension product in Group II patients was significantly different

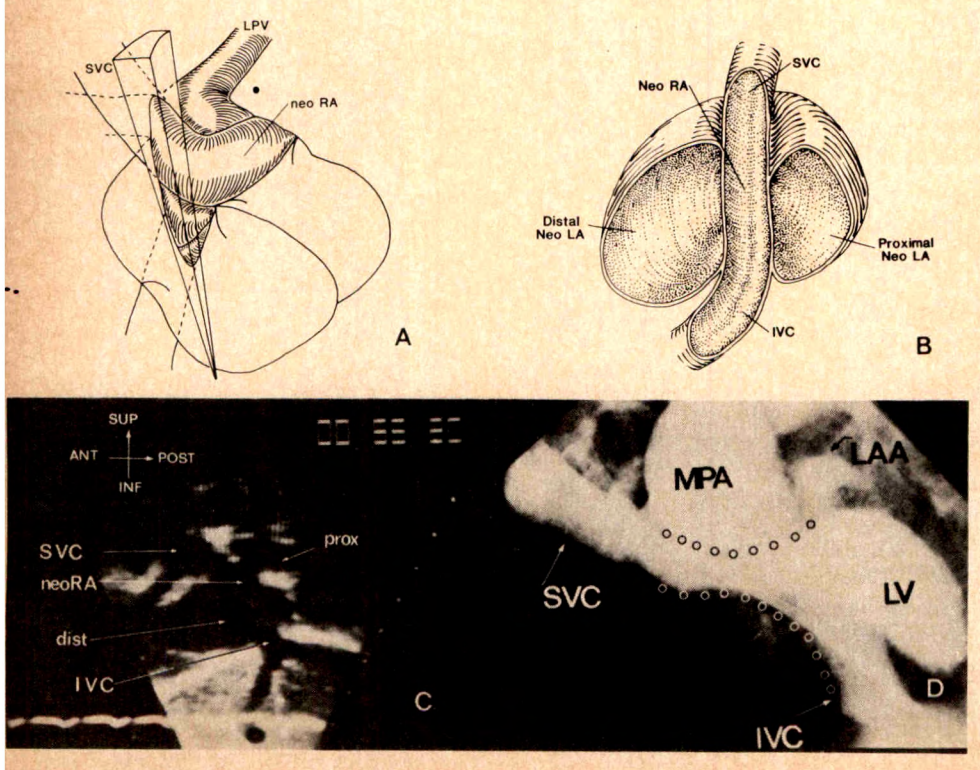

FIGURE 5. A, diagram of the transverse echocardiographic plane of the atria. The shaded structures are on the left side of the sector plane. **B,** diagram of the heart as it would appear if it were "cut open" along the sector plane. **C,** 2-D echocardiogram of Patient 6. The superior vena caval–neo-right atrial and inferior vena caval–neo-right atrial junctions are seen. The distal (dist) portion of the neo-left atrium, immediately above the tricuspid valve, lies anterior to the caval pathways. The proximal (prox) portion of the neo-left atrium, into which the pulmonary veins drain, lies posterior to the caval pathways. **D,** angiocardiogram of the venae cavae of a normal post-Senning patient not included in the study group, long axial oblique view. MPA = main pulmonary artery; other abbreviations as in Figure 1.

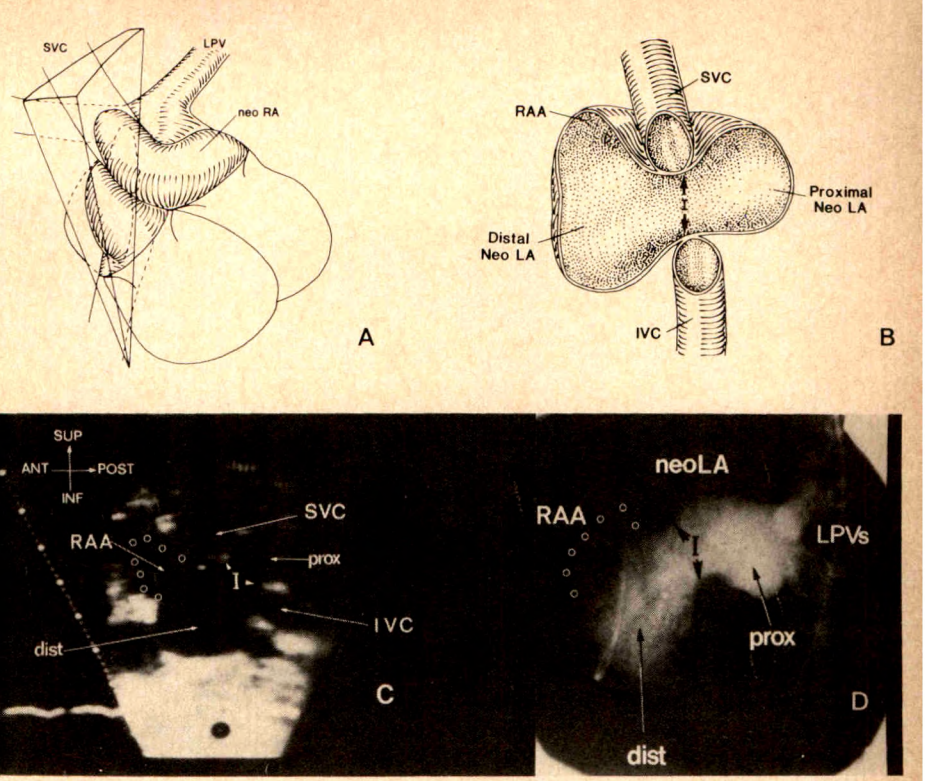

FIGURE 6. A, diagram of the modified transverse echocardiographic plane used to image the neo-left atrium. From the plane diagrammed in Figure 5A, the transducer is aimed slightly to the patient's right until the superior vena caval–neo-right atrial and inferior vena caval–neo-right atrial junctions are no longer visualized. The shaded structures are on the left side of the sector plane. **B,** diagram of the heart as it would appear if it were "cut open" along the sector plane. **C,** 2-D echocardiogram of the neo-left atrium of Patient 6, modified transverse view. The isthmus (I) connects the 2 portions (prox and dist) of the neo-left atrium. The **open circles** outline the border of the morphologic right atrial appendage (RAA), which is part of the distal neo-left atrium. **D,** angiocardiogram of the neo-left atrium of Patient 3, lateral view. The retrograde arterial catheter has been maneuvered from the right ventricular back across the tricuspid valve into the dist neo-left atrium and then into the proximal neo-left atrium, where contrast has been injected. The **open circles** outline the morphologic right atrial appendage (RAA).

($p < 0.05$, Wilcoxon rank-sum test) from Group I patients (Fig. 8A). Figure 9A illustrates the appearance of an obstructed superior vena caval pathway. In both Group II patients, the area of narrowing occurred at the junction of the superior vena cava with the neo-right atrium.

Group III (isolated pulmonary venous obstruction): The dimension of the pulmonary venous pathway in the 4-chamber view of 2 Group III patients was at the lower limits of normal, while the 4-chamber dimension of the other was clearly below normal (Fig. 7E). In the transverse view, the dimension of the pulmonary venous pathway for all 3 Group III patients was just outside the normal range (Fig. 7F). The pulmonary venous pathway dimension product in Group III patients was significantly smaller ($p < 0.01$) than in Group I patients (Fig. 8C). Figure 9, B and C, illustrates the isthmus of the neo-left atrium in a case of pulmonary venous obstruction.

Group IV (severe tricuspid regurgitation): In the 4-chamber view, the dimension of the pulmonary venous pathway was at the upper limits of normal in 2 of 4 Group IV patients and was larger than normal in the other 2 (Fig. 7E). In the transverse view, the pulmonary venous pathway dimension was larger than normal in all 4 Group IV patients (Fig. 7F). The pulmonary venous pathway dimension product in Group IV patients was significantly larger ($p < 0.01$) than Group I patients (Fig. 8C).

The 1 patient with concomitant superior vena caval and mild inferior vena caval obstruction had smaller than normal superior vena caval and inferior vena caval dimension products (Fig. 8, A and B). The 4 patients in Group IV were the only patients in this study with prominent systolic expansion of the neo-left atrium; all qualitatively exhibited enlargement of the entire neo-left atrium, not just the isthmus.

Group V (large residual ventricular septal defect): In the 1 Group V patient, the pulmonary venous pathway dimension was at the upper limits of normal in both the 4-chamber (Fig. 7E) and transverse (Fig. 7F) views. The dimension product was similarly at the upper range of normal (Fig. 8C). This patient did not have prominent systolic expansion of the neo-left atrium.

Interobserver variability: The mean difference in normalized caval dimension measurements between 2 independent observers in each of the 2 views was 1.1 mm, the maximum difference being 2.6 mm. The mean difference in normalized pulmonary venous pathway dimension measurements was 1.5 mm, the maximum difference being 4.5 mm in a patient with severe TR and giant neo-left atrium. Interobserver variability never resulted in dimension product overlap between the groups.

Discussion

The Mustard operation has been evaluated by 2-D echocardiography.[12] Systemic venous obstruction has been detected by 2-D contrast echocardiography,[13] pulsed Doppler echocardiography,[14,15] and radionuclide imaging.[16]

The modified Senning procedure is used by numerous institutions[1–4,6] with operative mortality rates as low as the published mortality rate for the Mustard operation.[17–19] Our study demonstrates the 2-D echocardiographic appearance of the caval and pulmonary venous pathways after the Senning procedure. Furthermore, we have given a range of normal values for the diameter of the caval and pulmonary venous pathways in the 4-chamber and transverse view. The dimension product

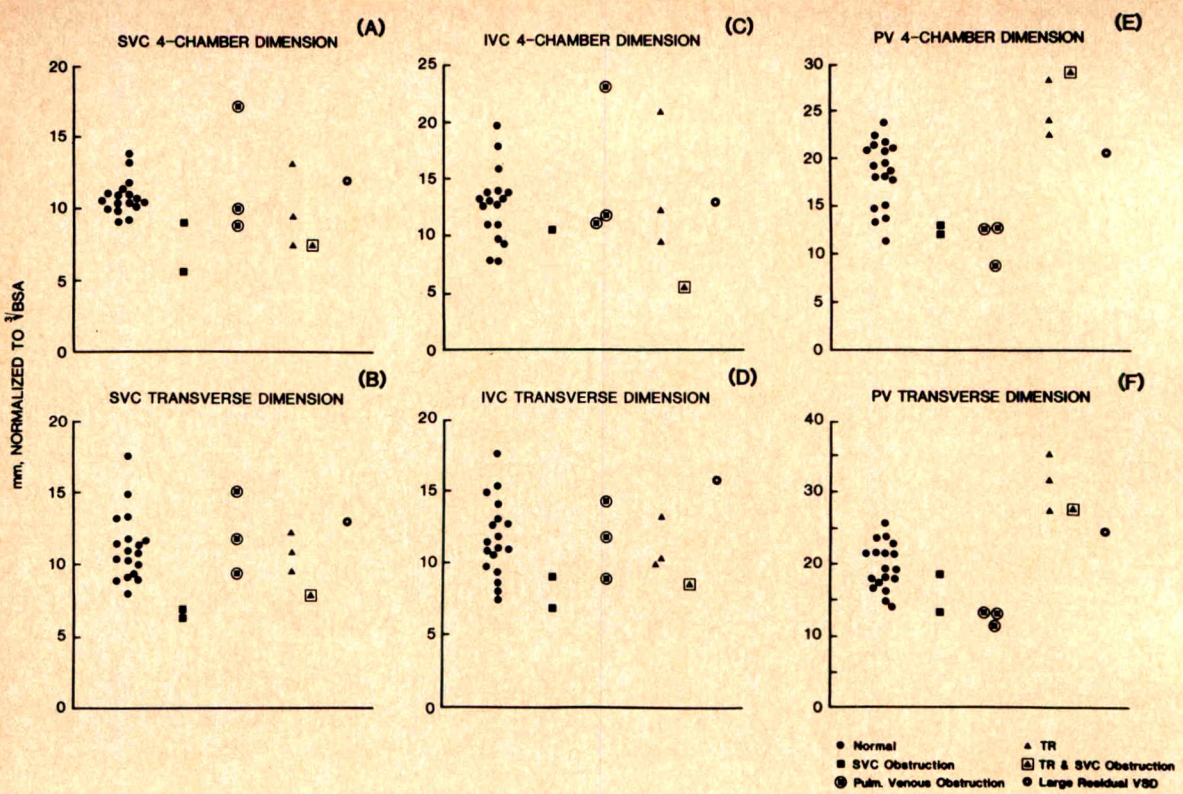

FIGURE 7. Normalized superior vena caval (SVC) dimension measurements in the 4-chamber view (**A**) and in the transverse view (**B**); normalized inferior vena caval (IVC) dimension measurements in the 4-chamber view (**C**) and in the transverse view (**D**); normalized pulmonary venous (PV) pathway dimension measurements in the 4-chamber view (**E**) and in the transverse view (**F**). For 1 of the 2 patients with isolated superior vena caval obstruction, the inferior vena caval 4-chamber dimension was not obtained. BSA = body surface area; TR = tricuspid regurgitation; VSD = ventricular septal defect.

parameter yielded better separation of "normal" post-Senning patients from those with catheterization-proven abnormalities than did either linear dimension alone.

This technique may also be able to detect multiple postoperative abnormalities if all are hemodynamically significant. The patient with combined severe TR and superior vena caval obstruction had both abnormal superior vena caval and pulmonary venous pathway dimension products.

Although the only patients to have the feature of prominent systolic expansion of the neo-left atrium were those with severe TR, we are uncertain if this echocardiographic sign is absolutely reliable in distinguishing TR from residual ventricular septal defect, 2 potential causes of neo-left atrium enlargement. The 1 patient with a large residual ventricular septal defect and minimal TR had a pulmonary venous pathway dimension product at the upper limits of normal but did not have prominent systolic expansion of the neo-left

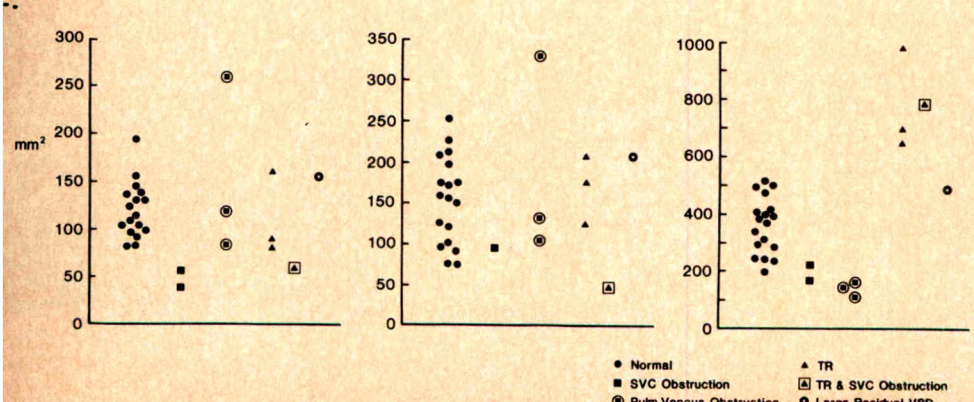

FIGURE 8. A, superior vena caval dimension products. **B,** inferior vena caval dimension products. **C,** pulmonary venous pathway dimension products. For each venous pathway, the dimension product is obtained by multiplying the normalized 4-chamber dimension by the normalized transverse dimension. For 1 of the 2 patients with isolated superior vena caval obstruction, the inferior vena caval dimension product could not be calculated because the inferior vena caval 4-chamber dimension was not obtained. Abbreviations as in Figure 7.

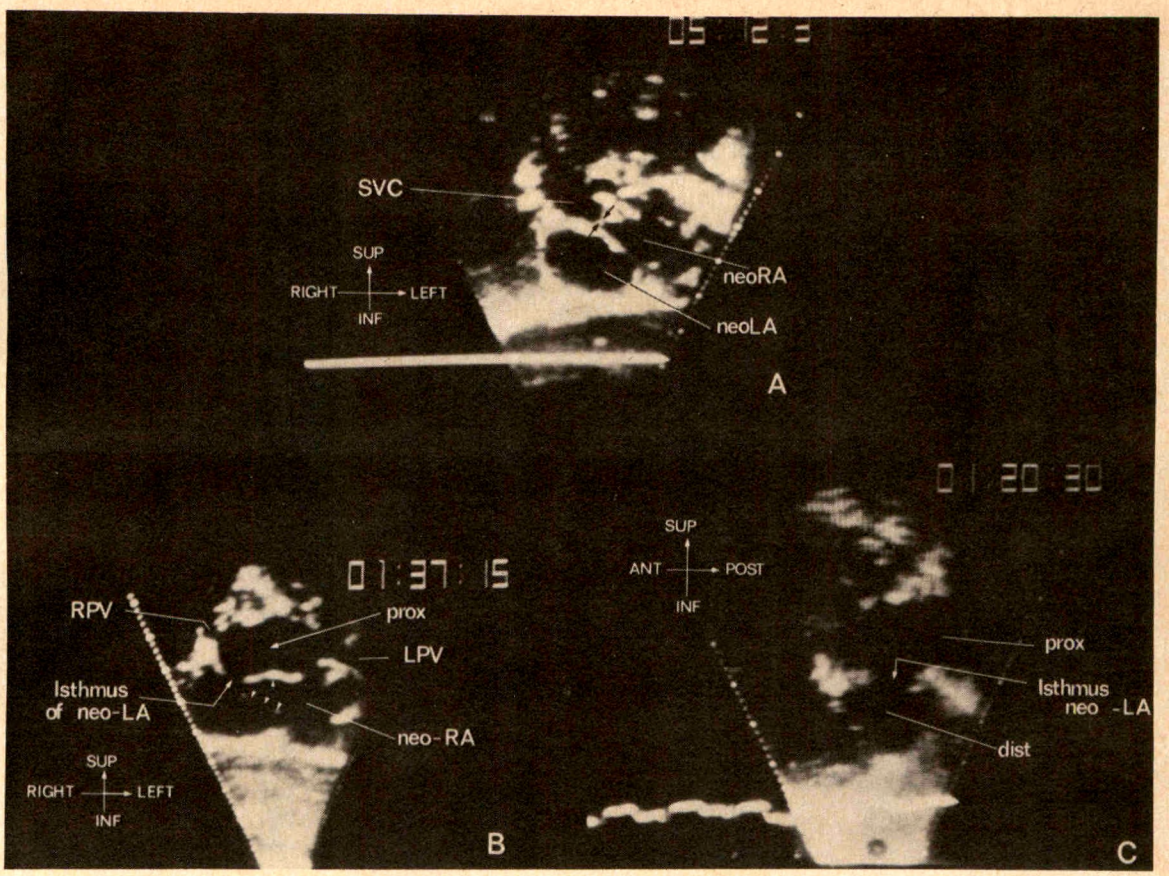

FIGURE 9. A, 2-D echocardiogram of the superior vena caval pathway of Patient 20, modified 4-chamber view. **Black arrowheads** show the narrow superior vena caval–neo-right atrial junction. Compare this with the normal superior vena caval pathway (Fig.3C). **B,** 2-D echocardiogram of Patient 23, 4-chamber view. The **white arrowheads** demonstrate the neo-atrial septum, separating the neo-right atrium from the neo-left atrium. This patient had severe pulmonary venous obstruction at cardiac catheterization. The narrowed isthmus as well as the dilated proximal (prox) portion of the neo-left atrium are visualized. Compare this image with the normal 4-chamber view (Fig. 2C). **C,** 2-D echocardiogram of Patient 23, modified transverse view. Note again the dilated proximal portion of the neo-left atrium and the narrowed isthmus. Compare with the modified transverse view of the neo-left atrium (Fig. 6C). Other abbreviations as in Figure 1.

atrium. More data are needed before we can conclude that systolic expansion of the neo-left atrium specifically indicates TR. We expect that eventually pulsed Doppler echocardiography will help distinguish between TR and residual ventricular septal defect.

Another theoretical limitation to judging TR by assessing neo-left atrium dimensions arises from the fact that patients with d-transposition and large ventricular septal defect usually have large atria before surgery. Presumably, the atria in these patients remain large for some time after the Senning procedure, even in the absence of residual defects. Therefore, interpreting abnormally large neo-left atrium dimensions in the very early postoperative period may be difficult in this group. Among our Group I patients were 3 patients with d-transposition of the great arteries and ventricular septal defect. It is reassuring that all of our Group IV (severe TR) patients had pulmonary venous pathway dimension products significantly higher than these 3 Group I patients. However, the echocardiographic data in these 3 Group I patients were obtained 13 to 17 months after operation rather than in the early postoperative period when the pulmonary venous pathway dimension might have been larger.

In addition, it appears that a large residual ventricular shunt may not always result in an abnormally large pulmonary venous pathway dimension product since our 1 Group V patient was still within the normal range.

Computer Interpretation of Pediatric Frank Vectorcardiograms in the Evaluation of Congenital Heart Disease

CHRISTIAN R. BROHET, MD, CHRISTIANE DERWAEL-BARCHY, BA, ANNIE ROBERT, MS, ROBERT FESLER, Eng, MADY STYNS, MD, LUCIEN A. BRASSEUR, MD, and ANDRÉ VLIERS, MD

The evaluation of a new computer program for analysis and interpretation of pediatric Frank vectorcardiograms is reported. The program includes extensive age- and sex-dependent criteria based on tables of limits for numerous vectorcardiographic parameters. In 728 catheterized patients, the diagnostic performance for type A statements was tested against independent and objective evidence obtained from hemodynamic and angiographic data. The overall diagnostic accuracy ranged from 75 to 89% without difference between children <2 years of age and those ≥2 years of age. Sensitivities and specificities of the various diagnoses did not differ much between the 2 age groups. In the younger children, the accuracy of a positive diagnosis of left ventricular hypertrophy, right ventricular hypertrophy, and biventricular hypertrophy was 20, 15, and 32% higher, respectively, than in the older children. The accuracy of the diagnosis "normal" was 28% lower in the younger children. These differences were explained by the higher proportion of pathologic findings in the younger children: 93% versus 74% in the older children.

Given the strict methods of the evaluation, the diagnostic accuracy of this pediatric program was considered clinically satisfactory. Program performance appears to be dependent not on patient age but on prevalence of abnormalities in the population analyzed. Further improvement can be expected by making the criteria more adaptable to the composition of the population.

As compared with computer systems of electrocardiographic analysis in adults, computerized pediatric electrocardiography has specific advantages. First, there are definitely fewer qualified readers of pediatric electrocardiograms, and they are certainly more poorly distributed. Second, the analysis of pediatric electrocardiograms is generally more difficult and requires a more quantitative approach than for adult electrocardiograms. This is due to the wide variation of the normal electrocardiogram from birth to adolescence and to the complexity of abnormalities produced by congenital heart diseases. Computer aid is thus most beneficial in this context, where diagnostic criteria must rely upon extensive use of tables with numerical values (such as for normal and abnormal ranges of amplitude, duration, and angular parameters). However, despite these advantages, there are few computer systems able to process pediatric electrocardiograms. Reports have been published on two 12-lead electrocardiographic analysis programs[1,2] and on 1 vectorcardiographic analysis program.[3] One institution has been routinely processing pediatric vectorcardiograms for some time,[4] and another is collecting a large data bank of pediatric Frank lead electrocardiograms.[5] Screening programs for children have been developed in Germany[6] and in Japan.[7]

Our own computer system of automated electrovectorcardiographic interpretation[8,9] has been extended to enable processing of pediatric Frank lead orthogonal electrocardiograms and vectorcardiograms. Among several advantages, the Frank lead system contains a similar amount of basic information[10] but has 4 times less data to process than the 12-lead electrocardiogram. The normal ranges of Frank electrocardiographic measurements have been extensively studied,[11–16] and their limits are generally narrower than those of 12-lead electrocardiograms.[17] More importantly, the analysis of the spatial vectorcardiogram obtained with the Frank lead system has much diagnostic potential in patients with congenital heart disease as shown by recent correlative studies.[18] This study reports our experience with the current version of the pediatric program rou-

tinely used for the interpretation of vectorcardiograms in children referred to our institution for the evaluation of congenital heart disease.

Methods

Description of the pediatric program: signal processing and analysis: The input to the pediatric program consists of 10 seconds of simultaneous X, Y, and Z Frank leads sampled at 500/second with 12-bit resolution. The routine which performs the QRS identification and typing is identical to that of the adult program.[8] The rhythm analysis is also basically the same,[19] with some accommodation for pediatric data. Techniques for removal of baseline drift and selective beat averaging allow the obtainment of a noise-free "averaged" P-QRS-T complex on which the rest of the analysis is undertaken. For wave recognition, the pediatric program uses a threshold-crossing method applied to spatial velocity curves to determine various fiducial points. This algorithm was tested on an early set of pediatric records[20] and it has been extensively validated in routinely processing more than 3,000 pediatric records. Since there remains a problem with accurate determination of onset of P wave in records with a very fast heart rate, the automatic interpretation of P-wave contours is being delayed until better algorithms are found. Feature extraction, production of a measurement matrix for selected parameters, and high-resolution vectorcardiographic loop display are the same as for the adult program.[21]

Description of the pediatric program: automatic interpretation of QRS-T contours: The diagnostic criteria are composed of numerous vectorcardiographic parameters, including scalar, planar, and spatial measurements. Both linear and angular values are used, as well as rotation of QRS loop in frontal, sagittal, and transverse planes. This direction of vectorcardiographic loop, as well as maximal and mean spatial QRS and T vectors and loop areas in the various spatial octants, are specific vectorcardiographic parameters used extensively for the diagnosis of ventricular hypertrophies. Most criteria take into account the normal limits of vectorcardiographic measurements according to the patient's age and sex. No clinical data other than age, sex, and information concerning digitalis administration are incorporated into the diagnostic criteria. The normal limits of vectorcardiographic parameters have been obtained by recording and analyzing Frank orthogonal electrocardiograms in 970 children and adolescents aged 2 to 19 years.[22] For children <2 years of age in whom we are still collecting normal records, we currently use normal data from the literature.[5,11,14–15,18] For children ≥2 years of age, we have established the normal limits for 280 vectorcardiographic parameters by using the percentile method[23] with specific statistical tests applied to angular data[24] in 8 different age and sex subgroups.

Because there is always some overlap between normal and abnormal ranges, one cannot rely solely on whether a normal limit is exceeded to decide that a given parameter belongs to the pathologic group. In fact, each diagnostic criterion is composed of several interrelated parameters, some of which have several thresholds. To perform a diagnostic classification, the program follows the deterministic method, that is, Boolean algebra and decision-tree logic.[8] The multiparameter-multithreshold approach allows avoidance of a common pitfall of this conventional deterministic method—the excessive sensitivity of the diagnostic flow to small variations in the value of single parameters.[25] All diagnostic criteria were carefully designed in order to reach the maximum sensitivity and specificity according to the characteristics of our clinical population. These diagnostic criteria were based on current knowledge issued from published data,[18,26–29] from personal studies,[30] and from personal experience in analyzing a huge number of pediatric vectorcardiograms validated by hemodynamic and angiographic studies.

Among the main diagnostic categories so far considered by the program are the following: ectopic sinus or atrial focus; preexcitation pattern (Wolff-Parkinson-White); ventricular conduction defects (both minor and major, such as right bundle branch block with or without right ventricular hypertrophy, left bundle branch block, left anterior fascicular block); left and right ventricular hypertrophies with the degree of severity; combined or biventricular hypertrophy, its degree of severity, and, if appropriate, the type of ventricular dominance; repolarization changes; QRS and T loops within normal limits; some special features, such as abnormal initial vectors suggesting ventricular inversion, pseudoinfarction pattern as in tricuspid atresia, and cardiomyopathies.

Evaluation of the pediatric program in terms of diagnostic accuracy: A formal evaluation of the diagnostic performance of this pediatric program was undertaken along the lines defined at the 10th Bethesda Conference of the American College of Cardiology.[31] Only the type B diagnostic statements, which refer to electrophysiologic events such as conduction disturbances, and the type C diagnostic statements, which are merely electrocardiographic descriptors, such as "nonspecific ST-T changes," were assessed according to the physician's interpretation. All type A diagnostic statements, such as left ventricular hypertrophy (LVH), right ventricular hypertrophy (RVH), biventricular hypertrophy (BVH), and absence of cardiovascular abnormalities (NORMAL), which refer to pathophysiologic states and anatomic lesions were validated, not by an electrocardiographer,[32] but exclusively by objective data obtained from hemodynamic and angiographic studies. Most patients underwent a left- and right-sided cardiac catheterization, a few had only a right-sided cardiac catheterization, and biplane cineventriculograms were performed in all. The criteria used to assign a given patient to a diagnostic category, the so-called "clinical diagnosis," are listed in Appendix A. The assignment of each record to a clinical diagnostic category was then made independently, without prior knowledge of the program's interpretation.

A classification matrix was built to compare vectorcardiographic diagnosis with the "true" clinical diagnosis. The results of the diagnostic classification by the program were assessed with respect to multigroup diagnosis, that is, the ability not only to correctly recognize the presence or absence of a given abnormality, but also to avoid making false-positive statements for other abnormalities. Thus, for each diagnostic category, analysis of the classification matrix allowed computation of numbers of true positives, false positives, false negatives, and true negatives and, from these figures, derivation of various indexes of diagnostic performance, such as sensitivity, specificity, accuracy of positive and negative diagnoses, and diagnostic accuracy, following the definitions and rules described in Appendix B.

Results

The study population consisted of a series of 728 young patients referred to our institution for evaluation of congenital heart disease by heart catheterization either as a diagnostic procedure or as preoperative or postoperative check-up. A Frank lead vectorcardiogram was routinely recorded in all these patients, usually on the same day and in no case more than 3 weeks from the invasive study. The clinical characteristics of this population are shown in Tables I and II. Table I lists the age and sex distribution of the patients. Table II shows

TABLE I Age and Sex Distribution of the 728 Catheterized Pediatric Patients

Age	Male	Female
≤1 week	1	1
≤1 month	8	13
≤3 months	22	11
≤6 months	17	23
≤12 months	41	50
≤24 months	27	28
2 to 5 years	162	133
6 to 10 years	64	35
11 to 15 years	37	34
16 to 19 years	10	11
Total	389	339

TABLE II Distribution of the Types of Congenital Heart Disease Among the 728 Catheterized Pediatric Patients

Disease	Number
Right ventricular pressure overload (n = 188)	
Tetralogy of Fallot	71
D-transposition of the great arteries	50
Ventricular septal defect with pulmonic stenosis or pulmonary hypertension	37
Pulmonic stenosis	30
Right ventricular volume overload (n = 77)	
Secundum atrial septal defect	72
Anomalous pulmonary venous return	5
Left ventricular pressure overload (n = 77)	
Aortic stenosis	39
Coarctation of the aorta	38
Left ventricular volume overload (n = 67)	
Patent ductus arteriosus	37
Mitral regurgitation	12
Aortic regurgitation	7
Tricuspid atresia	6
Pulmonic atresia (intact ventricular septum)	5
Combined ventricular overload (n = 173)	
Ventricular septal defect	97
Endocardial cushion defect	39
Multiple defects	18
Single ventricle	10
L-transposition of the great arteries	6
Truncus arteriosus	3
Miscellaneous cardiac anomalies (n = 59)	
Cardiomyopathies or anomalous origin of left coronary artery	17
Ebstein's anomaly	5
Other anomalies	37
No significant cardiovascular disease (n = 87)	

the disease spectrum according to the type of ventricular overloading.

The results of the program's interpretation were first evaluated on a set of 112 records; they were used to modify and optimize diagnostic criteria. This "learning set" was then reanalyzed and a larger "testing set" of 616 records was analyzed. Since there was no significant difference in the results obtained with the 2 sets of records, they were pooled and are presented for the total group of 728 records.

Accuracy of type A diagnostic statements: Since we expected more difficulties in the analysis of records belonging to very young patients, the results were analyzed separately in children <2 years of age and in those ≥2 years of age. The rate of completely correct classifications, that is, correct for diagnostic category and degree of severity or ventricular dominance, was about the same in the 2 age groups: 58% in the younger children and 59% in the older patients. The percentage of satisfactory classifications, that is, allowing for some disagreement about degree of severity or ventricular dominance, was higher in children ≥2 years of age, 73%, versus 67% in the children <2 years of age. In the younger patients, 10 of 16 children (63%) without significant cardiac lesions were correctly classified by the program as normal, whereas 187 of 205 pathologic records (91%) were correctly classified as abnormal. Only 18 patients had moderate to severe LVH (LVH++), of whom 10 (56%) were classified as having either LVH++ or BVH with left ventricular dominance. Sixty-seven of 83 patients (81%) with moderate to severe RVH (RVH++) were classified as having either RVH++ or BVH with right ventricular dominance. The 7 false-negative results misclassified as NORMAL belonged to infants in whom the right ventricular preponderance was considered physiologic. In 82 patients with BVH, 38 (46%) classifications were completely correct, and 50 (61%) were satisfactory, allowing for disagreement about degree of severity or ventricular dominance. In the older children, 61 of 104 records (59%) from normal patients were correctly classified as within normal limits. Twenty-two misclassifications were minor, corresponding to such statements as "possible mild" and "rule out LVH or RVH." Of 293 abnormal records, 258 (88%) were correctly classified in the pathologic group. Thirty-six of 57 cases (63%) with LVH++ as the clinical diagnosis were classified as either LVH++, severe BVH (BVH++), or BVH with left ventricular dominance. Seventeen were misclassified as mild or possible LVH(+) or BVH(+). There were 9 false-positive results for LVH in patients without significant anatomic LVH but whose left maximal spatial voltage was markedly increased. Of 106 patients with RVH++, 94 (89%) were correctly classified. Among 9 false-positive findings of RVH++, there were 4 patients who actually had LVH which produced a rightward posterior displacement of the maximal spatial QRS vector.[26] Thirteen of the 42 patients (31%) with BVH were correctly classified, including degree of severity and type of ventricular dominance. Twenty-six of the classifications of BVH were satisfactory (62%).

Table III shows the various indexes of diagnostic performance.[33] For the total group, sensitivity, specificity, and diagnostic accuracy were, respectively, for LVH: 69, 84, and 78%; for RVH: 84, 74, and 79%; for BVH: 61, 90, and 84%; and for NORMAL: 59, 89, and 84%. There were no striking differences between the 2 age groups. Only the specificity of LVH diagnosis was 10% higher in the younger children (92% versus 81%) and specificity of RVH diagnosis was 20% higher in the older children (77% versus 58%). More important differences between the 2 age groups were noted when results were expressed in terms of accuracy of positive and of negative diagnoses. Indeed, these indexes were influenced by the prevalence of the diagnoses in the population analyzed. So, in the younger children, in whom the prevalence of clinical LVH was higher (52% versus 40%), the accuracy of a positive diagnosis of LVH

TABLE III Diagnostic Performance of Computerized Pediatric Vectorcardiographic Interpretation: Type A Diagnostic Statements

Diagnostic Category	Age	n	Prevalence (%)	Sensitivity (%)	Specificity (%)	Accuracy of Positive Diagnosis (%)	Accuracy of Negative Diagnosis (%)	Diagnostic Accuracy (%)
LVH	<2 years	114	52	71	92	90	75	81
	≥2 years	158	40	67	81	70	79	76
	Total	272	44	69	84	78	77	78
RVH	<2 years	171	77	84	58	87	51	78
	≥2 years	167	42	84	77	73	87	80
	Total	338	55	84	74	79	79	79
BVH	<2 years	82	37	61	88	75	79	78
	≥2 years	42	11	62	90	43	95	87
	Total	124	20	61	90	59	90	84
None	<2 years	16	7	63	91	36	97	89
	≥2 years	104	26	59	88	64	86	80
	Total	120	19	59	89	57	90	84

BVH = biventricular hypertrophy; LVH = left ventricular hypertrophy; RVH = right ventricular hypertrophy.

was also higher (90% versus 70%). Likewise, in the older children, in whom the prevalence of clinical RVH was low (42% versus 77%), the accuracy of the negative diagnosis of RVH was higher than in the younger children (87% versus 51%). Differences were even more striking for the categories BVH and NORMAL. In the older children, in whom the prevalence of BVH was very low (11%), the accuracy of a negative statement was very high (95%); however, the predictive value of a positive diagnosis of BVH was only 43%, indicating that more than half of the BVH diagnoses were actually false. The predictive value of both a negative and a positive diagnosis of BVH was more satisfactory in the children <2 years of age in whom the prevalence of clinical BVH reached 37%. In the younger children, on the other hand, along with the low prevalence of normal heart (7%), the predictive value of the vectorcardiographic diagnosis of NORMAL was only 36%, whereas the accuracy of the diagnosis of any abnormality reached the value of 97%.

Accuracy of type B and type A + B diagnostic statements: The ability of the program to identify various kinds of ventricular conduction defects was satisfactory, as shown in Table IV. Of particular interest were results corresponding to special features of this program, such as the ability to diagnose RVH in the presence of complete right bundle branch block in 78% of the cases and the ability to draw the reader's attention to specific patterns, indicated in Table IV as "other major abnormalities," such as ectopic sinus or atrial focus, ventricular inversion, and pseudoinfarction as in tricuspid atresia or cardiomyopathy. On the whole, the classification of type B and type A + B statements were completely correct in 88% of the cases, and the accuracy rate for ventricular conduction defects (type B only) was 90%.

Discussion

Our study population consisted of an unselected series of pediatric patients without an attempt to have clear-cut cases. Various kinds of congenital heart disease, sometimes quite complex, were present in 88% of these children and many required surgical treatment. One hundred twenty of the 618 records with a type A diagnostic statement (19%) belonged to patients without significant hemodynamic lesions. In 81% of the records, the clinical diagnosis indicated the presence of LVH, RVH, or BVH, in various degrees, from mild to severe. According to the recommendations of Task Force III at the 10th Bethesda Conference,[31] all type A diagnostic statements were validated using objective data obtained independently of the electrocardiogram

TABLE IV Diagnostic Performance of Computerized Pediatric Vectorcardiographic Interpretation: Type B* and Type A + B† Diagnostic Statements

Diagnostic Category	Cases Called by Physician* and Cases Validated by Catheterization† (n)	Cases Called by Program	
		n	%
Right bundle branch block	79*	78	99
With RVH	55†	43	78
Without RVH	7†	5	
With left anterior hemiblock	14*	13	93
Left anterior hemiblock	79*	73	92
Left bundle branch block	2*	2	. . .
Preexcitation	7*	5	. . .
Minor ventricular conduction defect	35*	35	100
Other major abnormalities	19*,†	19	100

RVH = right ventricular hypertrophy.

as a reference standard, not the physician's opinion.[32] As far as we know, this is the first time a computer program routinely used for the interpretation of pediatric vectorcardiograms was tested against independent and objective evidence for the "true" diagnosis in a large number of cases. A strict methodology also implies that the performance of the program should be assessed with respect to multigroup classification, that is by considering simultaneously all the possible diagnoses and not only 1 category versus another, or normality versus abnormality.

The presentation of the results by means of several indexes of diagnostic performance[33] gives a complete picture of the capabilities of the pediatric program in its present environment. Sensitivity, specificity, and diagnostic accuracy represent intrinsic characteristics of a diagnostic test and these indexes are relatively independent of the composition of the test population. In contrast, the accuracy or predictive value of positive or negative results is a better expression of the diagnostic performance of a test in a given setting, since they are dependent on the prevalence of diagnostic categories in the tested population. These facts were exemplified by the differences of results in the 2 age groups. So, it appeared that in our infants and children <2 years of age, the prevalence of cardiac abnormalities was so high that the vectorcardiographic diagnosis "within normal limits" should always be questioned, since it has many chances to represent a false-negative statement. On the other hand, because of the high prevalence of BVH, the predictive value of this diagnosis was high. Conversely, in children ≥2 years of age, in whom a BVH was much rarer, this diagnosis corresponded to a false-positive result in about 50% of the cases. Thus, it is very unlikely that the same diagnostic criteria would give similar results in drastically different populations.

Given the type of our population with a high proportion of congenital cardiac lesions, and given the strict methods of the evaluation, the diagnostic classification of vectorcardiograms by the current version of the pediatric program gave promising results. As compared with the clinical diagnosis supplied by the hemodynamic and angiographic data, the program performed quite well in the diagnosis of BVH in young children. It is even possible that the method we employed gave an unfavorable picture of the program's behavior. Indeed, in some borderline cases, the clinical classification was forced into a given category because it was impossible to consider many different subsets. Also, cardiac catheterization, as compared with other sources of information such as echocardiography and radionuclide studies, is the "hardest" objective data which can be used to validate a noninvasive diagnostic test, but it is certainly not the only "gold standard."

Finally, it must be recalled that the automatic interpretation provided by the pediatric program has been evaluated in a blind fashion, without any knowledge of the clinical condition of the patient. In actual situations, the pediatrician almost always has some prior information about his patient's condition. He can use the results of the vectorcardiographic analysis in the frame of the total clinical picture. Our system of computer analysis of the pediatric vectorcardiogram must be viewed not as a substitute, but as an aid to the pediatric cardiologist, illustrating the concept of "computer-assisted electrocardiology." The speed of the recording procedure, the precision of the analysis, the production of numerous measurements and of high quality vector loops, and the storage and retrieval capabilities are elements perhaps as important as the automatic interpretation itself.

Appendix A: Criteria Used for Clinical Diagnosis

Left ventricular hypertrophy (LVH)

Left ventricular pressure overload, for example, aortic stenosis with increased peak systolic gradient (in mm Hg: 25 to 49 = mild, 50 to 79 = moderate, ≥80 = severe).

Left ventricular volume overload with large left-to-right shunts at ventricular or arterial level (pulmonic or systemic flow ratio $\dot{Q}p/\dot{Q}s \geq 1.5$); significant aortic or mitral regurgitation (grade 2 to 4).

Angiographic demonstration of increased left ventricular wall thickness or dilated left ventricular cavity, or both.

Right ventricular hypertrophy (RVH)

Right ventricular pressure overload, for example, pulmonary stenosis with increased peak systolic pressure gradient (in millimeters of mercury: 25 to 49 = mild, 50 to 79 = moderate, ≥80 = severe).

All left-to-right shunts with pulmonary hypertension or increased pulmonary-to-systemic resistance ratio (Rp/Rs: 0.2 to 0.5 = moderate, >0.5 = markedly increased, >0.7 = Eisenmenger complex).

All cyanotic diseases with systolic right ventricular pressure at near systemic levels.

Right ventricular volume overload with large left-to-right shunt at venous or atrial level ($\dot{Q}p/\dot{Q}s \geq 1.5$) and dilated right ventricular cavity.

Angiographic evidence of increased right ventricular wall thickness or dilated right ventricular cavity, or both.

Biventricular hypertrophy (BVH)

Any mixture of criteria of LVH and RVH.

NORMAL

No organic heart disease demonstrated by invasive studies or trivial abnormality without significant hemodynamic consequence, and normal ventricular wall thickness and cavity dimensions.

Appendix B: Definitions and Rules Used for the Assessment of Diagnostic Accuracy of the Pediatric Program

From the classification matrixes one can obtain, for each diagnostic category, the numbers of true-positive, false-positive, false-negative, and true-negative results.

True-positive (TP)

For LVH and RVH: patients with LVH or RVH by clinical diagnosis correctly classified as LVH or RVH, respectively, including same degree of severity plus those classified as BVH (any subcategory), and patients with BVH by clinical diagnosis, classified as LVH or RVH, respectively, or as BVH (any subcategory).

For BVH: only patients with BVH by clinical diagnosis correctly classified as BVH (any subcategory).

For NORMAL: only normal patients by clinical diagnosis correctly classified as normal by the program.

False-positive (FP)

For LVH: non-LVH patients (RVH, NORMAL) by clinical diagnosis misclassified as LVH or BVH, and mild LVH (LVH+) misclassified as marked LVH (LVH++).

For RVH: non-RVH patients (LVH, NORMAL) by clinical diagnosis misclassified as RVH or BVH, and mild RVH (RVH+) misclassified as marked RVH (RVH++).

For BVH: only non-BVH patients (LVH, RVH, NORMAL) by clinical diagnosis misclassified as BVH.

For NORMAL: abnormal patients (LVH, RVH, BVH, including mild cases) by clinical diagnosis misclassified as NORMAL.

False-negative:

For LVH: LVH and BVH patients missed and classified as either RVH or NORMAL, and moderate to severe LVH (LVH++) by clinical diagnosis misclassified as mild, possible LVH (LVH+).

For RVH: RVH and BVH patients missed and classified as either LVH or NORMAL, and moderate to severe RVH (RVH++) by clinical diagnosis misclassified as mild, possible RVH (RVH+).

For BVH: BVH patients missed and classified as either LVH, RVH, or NORMAL.

For NORMAL: NORMAL patients by clinical diagnosis misclassified as abnormal: LVH, RVH, or BVH, including "mild" diagnosis (+).

True-negative (TN)

For LVH, RVH, BVH: non-LVH, non-RVH, non-BVH patients correctly diagnosed.

For NORMAL: all abnormal patients diagnosed as abnormal.

From the numbers of true-positive (TP), false-positive (FP), false-negative (FN), and true-negative (TN) results, one can compute various indexes of diagnostic performance for each diagnostic category:

$$\text{Sensitivity} = [(TP)/(TP + FN)] \times 100.$$

$$\text{Specificity} = [(TN/(TN + FP)] \times 100.$$

$$\text{Accuracy of positive diagnosis} = [(TP)/(TP + FP)] \times 100.$$

$$\text{Accuracy of negative diagnosis} = [(TN)/(TN + FN)] \times 100.$$

$$\text{Diagnostic accuracy} = [(TP + TN)/(TP + TN + FP + FN)] \times 100.$$

Glucose and Insulin Changes in Infants and Children Undergoing Hypothermic Open-Heart Surgery

GEORGE BENZING III, MD, PAUL D. FRANCIS, MD, SAMUEL KAPLAN, MD, JAMES A. HELMSWORTH, MD, and MARK A. SPERLING, MD

Marked hyperglycemia was observed in patients undergoing hypothermic open-heart surgery. To evaluate potential mechanisms responsible for hyperglycemia, paired samples were evaluated for glucose and insulin levels in 3 groups of patients. Group 1 consisted of 8 patients <2 years of age undergoing cardiac surgery requiring total circulatory arrest; Group 2 consisted of 9 patients <2 years of age undergoing open-heart procedures but not requiring total circulatory arrest; Group 3 consisted of 10 patients >2 years of age, none of whom required total circulatory arrest. All 3 groups had striking hyperglycemia during cardiac surgery and in the first few hours after the operation. Despite elevated glucose levels during surgery, insulin levels failed to increase proportionately in response to hyperglycemic stimulus. Subsequently, in a fourth group of 10 patients <2 years of age not undergoing total circulatory arrest, the amount of glucose infused was restricted and they did not have hyperglycemia. In children, osmotic diuresis resulting from hyperglycemia after open-heart surgery may be misinterpreted as an index of satisfactory cardiorenal performance. Accordingly, it is recommended that the diluent added to the pump blood prime solution contain no supplemental glucose; also, intraoperative fluid should consist of a balanced electrolyte solution but no glucose.

In the care of infants and children with congenital heart disease, deep hypothermia with and without total circulatory arrest is used to facilitate open-heart surgery.[1–3] These techniques provide excellent conditions for surgical repair but may subject the patient to profound physiologic alterations.[4–6] One of the most important alterations induced during open-heart hypothermic surgery involves glucose homeostasis. Hyperglycemia and hypoinsulinemia have been documented during cardiac surgery of lower body temperatures in man[7–10] and experimental animals.[11,12] Some workers have found that children have a diminished and delayed insulin response compared with adults,[12] resulting in striking hyperglycemia in these patients.[13,14] The occurrence of hyperglycemia (with glucose levels >700 mg/dl) in 2 patients in our institution led us to evaluate the changes in glucose and insulin levels for infants and children undergoing deep hypothermic cardiovascular surgery. Since exogenous glucose was found to be the major cause of hyperglycemia, restricted infusion of glucose is proposed to prevent this complication in infants and children.

Methods

Thirty-seven nonconsecutive patients undergoing hypothermic open-heart surgery at the Children's Hospital Medical Center were evaluated. There was no evidence of diabetes mellitus or any other endocrine disorder in any of these patients. These patients were divided into 4 groups. Group 1 consisted of eight patients <2 years of age undergoing procedures requiring total circulatory arrest (TCA); 4 patients had a ventricular septal defect, 1 ostium primum, 2 transposition of the great arteries, and 1 aortic stenosis. Group 2 was composed of 10 patients <2 years of age but not requiring TCA; 8 had ventricular septal defect, and 2 had an atrioventricular canal. Group 3 consisted of 9 patients >2 years of age and not requiring TCA; 1 had a ventricular septal defect, 1 transposition of the great arteries, 1 tricuspid atresia, 2 an atrioventricular canal, 1 pulmonic stenosis, 2 tetralogy of Fallot, and 1 a rhabdomyoma of the right ventricle. After the initial findings in Groups 1 to 3, a fourth group was also

evaluated, composed of 10 patients <2 years not subjected to TCA but receiving restricted glucose output (Group 4).

All patients received premedication with a combination of atropine, ketamine, morphine, pentobarbital, or fentanyl. Deep anesthesia was induced with ketamine and maintained with nitrous oxide, oxygen, d-tubocurarine, pancuronium, morphine, or a combination of these.

All patients were subjected to cardiopulmonary bypass and cooled to a core temperature of 20°C ± 2°C (mean ± SD). The pump perfusion rate was approximately 100 ml/kg/min during hypothermia and 200 ml/kg/min during rewarming. In Groups 1 to 3, the pump priming solution contained blood bank whole blood diluted to a hematocrit of 25 to 30% with 5% dextrose in a lactated Ringer's solution. For Group 4, a nonglucose electrolyte solution (Normosol-R) was substituted for 5% dextrose lactated Ringer's solution in the pump prime. For Groups 1 to 3, routine intravenous fluids contained 5% dextrose. Group 4 received intravenous electrolyte solution without additional glucose. Maintenance potassium was administered during surgery and additional intravenous potassium was given if the serum level decreased to <4.5 mEq/liter. Blood was administered postoperatively to maintain the hematocrit in a range of 30 to 40%.

Group 1 patients were subjected to a period of TCA ranging from 21 to 61 minutes (mean 36). Group 2, 3, and 4 had average intervals of hypothermic myocardial ischemia of 34, 40, and 35 minutes, respectively. Paired blood samples were obtained from an indwelling arterial line for glucose and insulin determinations. Glucose level was measured by a glucose oxidase technique.[15] Mean values are provided for each group ± standard deviation.

Insulin was assayed utilizing a double antibody radioimmunoassay technique as previously described.[15] In our institution, the normal fasting values for glucose range from 50 to 105 mg/dl. Normal values for fasting insulin range from 5 to 10 μU/ml.

Blood samples for Groups 1, 2, and 3 were obtained at the following times: under anesthesia while the patient was receiving intravenous glucose but before the initiation of cardiopulmonary bypass; 5 minutes after the start of bypass; at the beginning of rewarming; at the end of rewarming; and at 1, 2, 3, 4, and 24 hours after perfusion. A record was kept of all intravenous glucose received both in the operating room and in the postoperative period. Group 4 received a restricted glucose input. Neither the pump priming solution nor the routine intraoperative intravenous solution contained any glucose. Blood samples for glucose were obtained 1 hour after perfusion.

Data were analyzed using the Student paired and two-tailed *t* test with $p < 0.05$ considered significant.

Results

The mean body weight of Group 1 was 5.3 ± 1.9 kg and was significantly less ($p < 0.01$) than the Group 2 weight of 8.8 ± 1.9 kg. The mean body weight of Group 3 was 13.1 ± 3.0 kg and was significantly greater than that of Group 1 ($p < 0.01$) and Group 2 ($p < 0.01$).

The pump priming solution of all 3 groups contained a mean of 246 mg/dl of glucose. There was no significant difference in the glucose content of the 3 groups.

The mean rate of intravenous infusion of glucose in the operating room was 11.5 ± 6.4 mg/kg/min in Group 1, which was significantly more than Group 2 (5.8 ± 4.1 mg/kg/min; $p < 0.05$). Group 1 also received significantly more than Group 3 (5.2 ± 2.3; $p < 0.05$). Group 2 did not differ from Group 3. Postoperatively, the rate of glucose infusion in all groups of patients ranged from 1.15 to 1.35 mg/kg/min. There was no significant difference among the groups of patients.

In Group 1 (Table I) there was a significant increase in the blood glucose concentration from a mean value of 303 ± 51 mg/dl soon after the onset of cardiopulmonary bypass to 327 ± 69 mg/dl at the time of reinstitution of bypass after TCA. Also, a significant ($p < 0.05$) decrease in the glucose level occurred from the end of the rewarming of the patient (347 ± 51 mg/dl) compared with that observed 2 hours after bypass (293 ± 66 mg/dl) and was significantly different again 3 hours after bypass (322 ± 80 mg/dl). From 4 to 24 hours postoperatively, the glucose level decreased significantly ($p < 0.001$) from 305 ± 85 mg/dl to 114 ± 24 mg/dl.

The insulin levels of Group 1 increase significantly ($p < 0.05$) from 8.8 ± 6.0 μU/ml at the time of reinstitution of perfusion after TCA to 16.9 ± 11.4 μU/ml at the end of rewarming the patient. One hour after rewarming, the insulin level decreased significantly to 7.6 ± 2.84 μU/ml ($p < 0.05$).

In Group 2 (Table II), the mean glucose level at the end of rewarming was 268 ± 41 mg/dl and decreased significantly to 215 ± 57 mg/dl 4 hours postoperatively ($p < 0.05$). The glucose concentration decreased significantly ($p < 0.05$) to 120 ± 24 mg/dl 24 hours postoperatively.

From the end of the hypothermic state during bypass, the insulin level of Group 2 increased significantly ($p < 0.01$) from 5.4 ± 2.4 to 16.8 ± 11.9 μU/ml. When compared with the end of rewarming, insulin levels observed at 1, 2, 3, and 4 hours postoperatively declined significantly ($p < 0.05$) to 8.8 ± 2.8, 8.4 ± 1.3, 8.0 ± 1.7, and 7.9 ± 3.0 μU/ml, respectively.

The glucose levels in Group 3 increased significantly ($p < 0.05$) for a mean of 253 ± 43 mg/dl soon after perfusion was instituted, to 277 ± 50 mg/dl at the end of hypothermia. Subsequently, the glucose level of 268 ± 95 mg/dl at a time of 4 hours postoperatively decreased significantly ($p < 0.01$) to 138 ± 45 mg/dl 24 hours postoperatively.

The insulin levels of Group 3 (Table III) decreased significantly ($p < 0.01$) soon after the onset of perfusion from a mean of 16.0 ± 9.5 μU/ml to 6.1 ± 4.4 μU/ml at

the end of hypothermia. From the end of the hypothermic state to the end of the rewarming, the mean insulin levels increased significantly ($p < 0.01$) from 6.1 ± 4.4 to 48.9 ± 43 μU/ml. Insulin levels of Group 3 decreased significantly from the end of the rewarming period to 12.6 ± 3.5, 14.9 ± 6.3, 14.9 ± 5.8, and 15.3 ± 6.3 μU/ml at 1, 2, 3, and 4 hours postoperatively ($p < 0.05$), respectively. When other comparisons of glucose and insulin levels were made within Groups 1, 2, and 3, no significant differences were observed using the paired *t* test.

The insulin to glucose ratios for Groups 2 and 3 decreased during the period of cardiopulmonary bypass and deep hypothermia. There was an increase in all 3 groups in response to rewarming, followed by a substantial decrease in the first postoperative hour. Twenty-four hours after surgery, Groups 1 and 2 were found to have normal insulin to glucose ratios but Group 3 had a greater value.

In Group 4, mean weight was 8.7 ± 4.0 kg. The mean serum glucose concentration was 126 ± 28 mg/dl 1 hour after perfusion, compared with values of 339 ± 69 mg/dl for Group 1, 284 ± 55 mg/dl for Group 2, and 296 ± 55 mg/dl for Group 3. The latter 3 groups differ significantly from Group 4 ($p < 0.001$).

Discussion

During the present study, hyperglycemia and hypoinsulinemia were documented in infants and children undergoing hypothermic surgery. Blood glucose levels have been noted previously to be increased during hypothermic cardiac surgery.[4,7,9,14,16–18] This elevation of blood glucose level could result from excessive exogenous glucose infusion, alteration of hormonal levels affecting glucose hemeostasis including decreased or delayed insulin response to hyperglycemia, and decreased peripheral glucose utilization. Our results suggest that a combination of diminished insulin response and excessive glucose infusion accounts for the hyperglycemia.

Hypothermia has been proposed as a primary mechanism for the reduction of insulin secretion by inhibition of the pancreatic secretory process.[11,14,18,19] However, other evidence indicates that insulin secretion is diminished with open-heart surgery even under normothermic conditions.[20] Furthermore, Baum and Porte[10] found that inhibition of insulin secretion could be reversed under conditions of deep hypothermia, suggesting that inhibition of metabolic processes by hypothermia is not the sole factor responsible. In view of the fact that insulin levels decreased 1 hour after surgery when our patients were normothermic, our data suggest that hypothermia is not the primary factor. Hypokalemia and hypocalcemia have also been shown to inhibit insulin release,[4,21,22] but these factors have not been consistently implicated.[4,23,24] The patients in our study were carefully monitored for electrolyte abnormalities both intraoperatively and postoperatively. We found no consistent relationship between levels of potassium or calcium or both and hyperglycemia. This is in agreement with results published by Moffitt et al[25] who showed an elevated glucose level in spite of intraoperative normokalemia and normocalcemia.

Diminished pancreatic blood flow would also cause decreased insulin secretion.[26] The cardiac output is redistributed during deep hypothermia with little decrease in cerebral and coronary flow but a marked decrease in splanchnic, including pancreatic, flow.[27,28] TCA would further compromise pancreatic perfusion and may thus inhibit insulin release. However, Baum and Porte[10] observed no reversal in the inhibition of insulin release with alpha-adrenergic vasodilators and they proposed therefore that blood flow alone was not responsible for this effect. Results from other studies would suggest that diminished pancreatic perfusion is one of the main factors causing hypoinsulinemia.[29,30]

In our study, we noted that the lowest level of insulin occurred during periods of hypothermia and low perfusion rates. The insulin response was improved during rewarming when total body perfusion was maintained by the heart-lung machine. We speculate that cardiac output decreased when patients were taken off bypass and a comcomitant decrease in insulin level was observed. Hyperglycemia was sustained by exogenous intravenous glucose infusion.

When the glucose concentration of the heart-lung machine before the onset of bypass is similar to that of the patient and is also similar at the time perfusion is

discontinued, then the pump prime solution may make little contribution to the glucose homeostasis of the patient. This assumes that the volume of fluid in the heart-lung machine initially and at termination of bypass are equal, which may not always be true. However, blood discarded by suction intraoperatively and postoperatively may compensate for differences. The glucose infused intravenously, however, is more significant.

From our observations, excessive glucose is administered intravenously in the operating room. The smaller the child, the proportionately greater is the amount of excessive glucose infused. Since the insulin level was depressed during these operative procedures, it would seem prudent to restrict glucose input in the operating room. Similarly, Freidenberg et al[31] recommended caution in the use of glucose-containing solution during the postoperative management of patients undergoing cranial surgery. These investigators reported severe hyperglycemia with coma in patients who had diabetes insipidus while receiving dexamethasone, an antagonist of insulin action. Excessive fluid loss by way of polyuria was replaced with glucose-containing solutions; this compounded fluid loss by inducing an osmotic diuresis superimposed on the diabetes insipidus. The problem was resolved by avoiding glucose solutions in combination with appropriate use of antidiuretic hormone. Hyperglycemia of the magnitude observed in our patients in combination with the low insulin levels indicates that glucose was not being metabolized. Such hyperglycemia would also cause an osmotic diuresis. Since urine output is used as one measure of assessing the adequacy of cardiorenal performance, osmotic diuresis may be misinterpreted as a salutary response. Thus, prevention of hyperglycemia is of value in patient care. Furthermore, we have documented no disadvantage to restriction of glucose input in the operating room. Postoperatively, we have found no need to change the glucose infusion rate from that usually employed. When exogenous glucose was eliminated from the intravenous electrolyte fluids, hyperglycemia did not occur (Group 4).

Cardioselective*

Lopressor®

metoprolol tartrate

is now

Once-a-day

New dosage schedule: To start, 100 mg once-a-day, or in divided doses
Dosage range: 100 mg – 450 mg daily

Lower doses (especially 100 mg) may not maintain full effect at end of 24-hour period. Measure BP near end of dosing interval, adjust to larger or more frequent dosage if needed.

*exerts a relative preference for beta-one receptors; this preference is not absolute

100-mg tablets

Please turn page for brief Prescribing Information.

Geigy

536-5763-A

A115

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure: Continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage in Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications, Warnings,** and **Precautions.**

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings.**

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

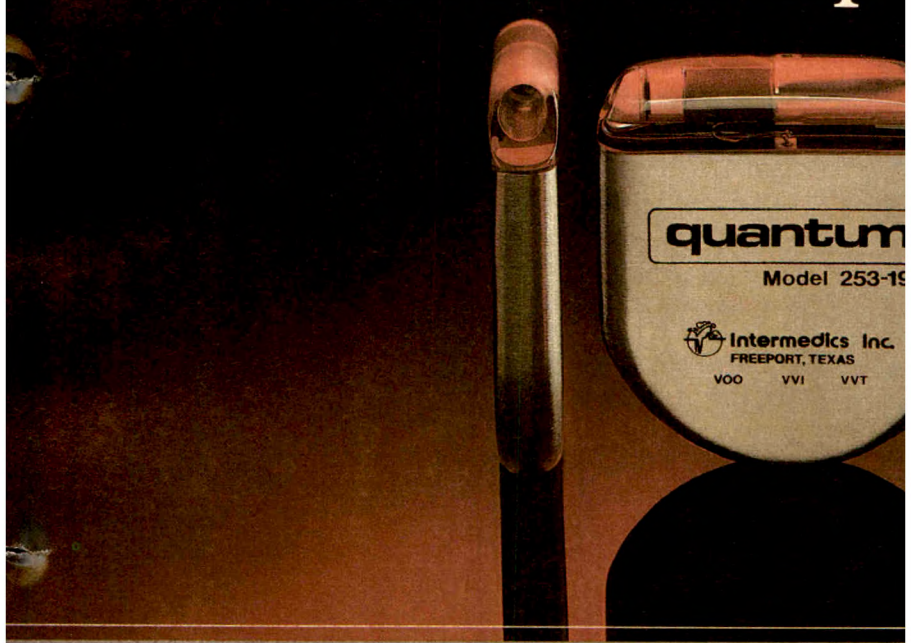
THE NEW QUANTUM™ P

8mm TH

And in better shape



MORE PHYSIOLOGICALLY COMPATIBLE SHAPE.
The new thin oval shape of the model 253-19 unipolar Quantum is designed to fit more comfortably into a smaller pocket with less tissue irritation. No upward cut into the fascia is necessary, and the pacemaker stays more securely in place.

LESS HASSLE—A NEW INTER-LOCK™ LEAD CONNECTOR SYSTEM.
The model 253-19 incorporates the innovative Inter-Lock™ lead connector system. This new, easy-to-use system requires no set screw assembly and allows leads to connect quickly and easily into place without the handling of loose screws or caps.

SMALLER SIZE, SAME FULL QUANTUM CAPABILITIES.
The model 253-19 unipolar Quantum 8mm features the same advanced measured telemetry, full multiprogrammability and transtelephonic capabilities as our other Quantum pacemakers.

The new, more convenient unit houses the same proven circuitry that makes Quantum a complete patient management system. Over 10,000 prescription programming combinations plus measured telemetry allow the physician to adjust the pacemaker to the patient's changing needs. Both operating and programmed data are available in digital read-out or hard copy form to help in making better, faster clinical decisions.

The unique new connector system, plus the thinner, lighter, more physiologically compatible shape of the new Quantum

pacemaker, is

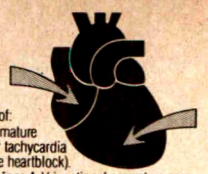
QUINAGLUTE
(quinidine gluconate)

QUINAGLUTE®
(quinidine gluconate)
DURA-TABS®



INDICATIONS AND USAGE: Quinaglute (quinidine gluconate) Dura-Tabs are indicated in the prevention and/or treatment of:
1. Ventricular arrhythmias: Premature ventricular contractions, ventricular tachycardia (when not associated with complete heartblock).
2. Junctional (nodal) arrhythmias: A-V junctional premature complexes, paroxysmal junctional tachycardia. **3. Supraventricular (atrial) arrhythmias:** Premature atrial contractions, paroxysmal atrial tachycardia, atrial flutter, atrial fibrillation (chronic and paroxysmal).
CONTRAINDICATIONS: 1. Idiosyncrasy or hypersensitivity to quinidine. 2. Complete A-V block. 3. Complete bundle branch block or other severe intraventricular conduction defects, especially those exhibiting a marked grade of QRS widening. 4. Digitalis intoxication manifested by A-V conduction disorders. 5. Myasthenia gravis. 6. Aberrant impulses and abnormal rhythms due to escape mechanisms.
WARNINGS: 1. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by a progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely rapid ventricular rate. This possible hazard may be reduced by digitalization prior to administration of quinidine. 2. Recent reports indicate that plasma concentrations of digoxin increase and may even double when quinidine is administered concurrently. Patients on concomitant therapy should be carefully monitored. Reduction of digoxin dosage may have to be considered. 3. Manifestations of quinidine cardiotoxicity such as excessive prolongation of the Q-T interval, widening of the QRS complex and ventricular tachyarrhythmias mandate immediate discontinuation of the drug and/or close clinical and electrocardiographic monitoring. 4. In susceptible individuals, such as those with marginally compensated cardiovascular disease, quinidine may produce clinically important depression of cardiac function such as hypotension, bradycardia, or heartblock. Quinidine therapy should be carefully monitored in such individuals. 5. Quinidine should be used with extreme caution in patients with incomplete A-V block since complete block and asystole may be produced. Quinidine may cause abnormalities of cardiac rhythm in digitalized patients and therefore should be used with caution in the presence of digitalis intoxication. 6. Quinidine should be used with caution in patients exhibiting renal, cardiac or hepatic insufficiency because of potential accumulation of quinidine in plasma leading to toxicity. 7. Patients taking quinidine occasionally have syncopal episodes which usually result from ventricular tachycardia or fibrillation. This syndrome has not been shown to be related to dose or plasma levels. Syncopal episodes frequently terminate spontaneously or in response to treatment, but sometimes are fatal. 8. A few cases of hepatotoxicity, including granulomatous hepatitis, due to quinidine hypersensitivity have been reported in patients taking quinidine. Unexplained fever and/or elevation of hepatic enzymes, particularly in the early stages of therapy, warrant consideration of possible hepatotoxicity. Monitoring liver function during the first 4-8 weeks should be considered. Cessation of quinidine in these cases usually results in the disappearance of toxicity.
PRECAUTIONS: General: The precautions to be observed include all those applicable to quinidine. A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncrasy to quinidine. Hypersensitivity to quinidine, although rare, should constantly be considered, especially during the first weeks of therapy. Hospitalization for close clinical observation, electrocardiographic monitoring, and possible determination of plasma quinidine levels is indicated when large doses are used, or with patients who present an increased risk.
Drug Interactions:

Drug	*Effect*
Quinidine with anticholinergic drugs	Additive vagolytic effect
Quinidine with cholinergic drugs	Antagonism of cholinergic effects
Quinidine with carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreased excretion of quinidine
Quinidine with coumarin anticoagulants	Reduction of clotting factor concentrations
Quinidine with tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade
Quinidine with phenothiazines and reserpine	Additive cardiac depressive effects
Quinidine with hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine
Quinidine with digoxin	Increased plasma concentrations of digoxin (see WARNINGS)

Carcinogenesis, Mutagenesis and Impairment of Fertility: Long-term studies in animals have not been performed to evaluate the carcinogenic potential of quinidine. There is currently no evidence of quinidine-induced mutagenesis or impairment of fertility.
Pregnancy: *Teratogenic Effects:* Pregnancy Category C. Animal reproduction studies have not been conducted with quinidine. There are no adequate and well-controlled studies in pregnant women. Quinaglute (quinidine gluconate) Dura-Tabs should be given to a pregnant woman only if clearly needed. *Nonteratogenic Effects:* Like quinine, quinidine has been reported to have oxytocic properties. The significance of this property in the clinical setting has not been established.
Nursing Mothers: Caution should be exercised when Quinaglute (quinidine gluconate) Dura-Tabs are administered to a nursing woman due to passage of the drug into breast milk.
Pediatric Use: There are no adequate and well-controlled studies establishing the safety and effectiveness of Quinaglute (quinidine gluconate) Dura-Tabs in children.
ADVERSE REACTIONS: Symptoms of cinchonism, ringing in ears, headache, nausea, and/or disturbed vision may appear in sensitive patients after a single dose of the drug. The most frequently encountered side effects to quinidine are gastrointestinal in nature. These gastrointestinal effects include nausea, vomiting, abdominal pain and diarrhea.
Less frequently encountered adverse reactions:
Cardiovascular: Widening of QRS complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms including ventricular tachycardia and fibrillation, paradoxical tachycardia, arterial embolism and hypotension.
Hematologic: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenia (purpura), agranulocytosis.
Central Nervous System: Headache, fever, vertigo, apprehension, excitement, confusion, delirium and syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasis, blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, night blindness, scotomata), optic neuritis.
Dermatologic: Rash, cutaneous flushing with intense pruritus, urticaria. Photosensitivity has also been reported.
Hypersensitivity Reactions: Angioedema, acute asthmatic episode, vascular collapse, respiratory arrest, hepatic toxicity, including granulomatous hepatitis (see WARNINGS). Although extremely rare, there have also been reports of lupus erythematosus in patients taking quinidine. A positive association with quinidine therapy has not been established.
See package insert for full information.

Announcing the comprehensive study of...the most fascinating syndrome in Cardiology...

THE PRE-EXCITATION SYNDROME: FACTS AND THEORIES

Libi Sherf, MD, FACC
Assoc. Professor of Cardiology, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine, and Visiting Assoc. Professor, Dept. of Medicine, University of Alabama.

Henry N. Neufeld, MD, FACC
Professor of Medicine and Chaim Sheba Professor of Cardiology, Chief, Heart Institute, Chaim Sheba Medical Center, Tel Hashomer, University of Tel Aviv—Sackler School of Medicine.

Every cardiologist, internist, pediatrician, surgeon—indeed, *every physician*—should have a good basic knowledge of the Pre-excitation Syndrome. Here are just a few reasons why this is so essential:

- ☐ ⅓ of all pre-excitation cases are misdiagnosed.
- ☐ 5% to 10% of all tachycardias in adults are produced by pre-excitation.
- ☐ In ½ of all infants under 10 months of age with life-threatening tachycardias, the tachycardias are actually secondary to pre-excitation.
- ☐ ⅓ to ½ of all children with pre-excitation have an additional heart disease.

Starting with Wolff, Parkinson and White's classic paper, this book gives a comprehensive summary of all important facts of pre-excitation, plus the authors' personal experiences of follow-up studies of patients through many decades. It also brings a broad view of the literature and discusses the different structural and physiological aspects which form the pathomechanism of pre-excitation.

"What is offered richly in this book is a methodical and comprehensive analysis of virtually all currently available knowledge on the subject. This is done with an admirable even-handedness, dealing objectively with all viewpoints but at the same time evaluating relative strengths and weaknesses of each observation and hypothesis. There is brought a wisdom here which only time and experience can provide. The encyclopedic references alone would make the book invaluable to anyone seriously interested in the Wolff-Parkinson-White syndrome. But when knowledgeable discussion and personal observations are added, it is genuinely a monumental contribution to clinical cardiology and cardiac electrophysiology."

Thomas N. James, MD
The Mary Gertrude Waters Professor of Cardiology and Chairman of the Department of Medicine, The University of Alabama in Birmingham, and Physician-in-Chief, University of Alabama Hospitals.

Cardiac Amyloidosis Causing Cardiac Dysfunction: Analysis of 54 Necropsy Patients

WILLIAM C. ROBERTS, MD and BRUCE F. WALLER, MD

Clinical and morphologic findings are described in 54 necropsy patients (32 men [59%]) aged 21 to 97 years (mean 64) with cardiac amyloid deposits extensive enough to cause fatal cardiac dysfunction. Chronic congestive heart failure (CHF) was present in 46 (85%). The duration of CHF, known in 39 patients, ranged from 1 to 108 months (mean 18) and lasted ≤12 months in 25 patients (64%). All 8 patients without CHF died suddenly and unexpectedly. Systemic arterial pressures were recorded in the last 3 months of life in 43 patients: the peak indirect systolic pressure was ≤130 mm Hg and the diastolic pressure <90 mm Hg in all. Electrocardiograms, recorded in the last 6 months of life in 40 patients, were abnormal in each: low voltage in 35 (63%); "myocardial infarction pattern" in 33 (83%); abnormal QRS axis in 29 (73%); arrhythmias in 29 (73%); first, second, or third degree heart block in 28 (45%); and complete bundle branch block in 7 (18%). In 30 patients, the QRS amplitude in all 12 leads was measured: in the 15 men it ranged from 60 to 197 mm (mean 99) (10 mm = 1 mV) and in the 15 women from 58 to 199 mm (mean 109). Diagnosis of amyloidosis was established by biopsy of noncardiac organs or tissues during life in only 18 (33%) patients. During life the condition simulated hypertrophic cardiomyopathy in 5 patients, constrictive pericardial disease in 3, and coronary heart disease (because of angina pectoris) in 4.

At necropsy, the hearts ranged in weight from 300 to 900 g (mean 554), and all but 1 had a "rubbery," noncompliant consistency. In addition to their presence in myocardial interstitium (53 patients) and in intramural coronary arteries (54 patients), amyloid deposits were present grossly in mural endocardium in all 54 patients and in valvular endocardium in 46 (85%). The cardiac ventricles were not dilated in 43 patients (80%), but both atria were dilated in all 54 patients. Intracardiac thrombi were present in 14 patients (26%). Cardiac amyloidosis must be considered in any elderly patient with chronic CHF unassociated with chest pain when blood pressure is normal and the electrocardiogram discloses low voltage and a pattern of "healed myocardial infarction."

In 1970, clinical and necropsy findings in 15 patients with cardiac dysfunction secondary to cardiac amyloidosis were reported from this laboratory.[1] During the past 13 years we have studied at necropsy an additional 39 patients with fatal cardiac amyloidosis. This report summarizes clinical and morphologic findings in these 54 patients with cardiac amyloid deposits extensive enough to cause cardiac dysfunction, with particular emphasis on electrocardiographic observations.

Patients Studied and Findings

Clinical findings: The 54 patients ranged in age at death from 21 to 97 years (mean 64). The 32 men (59%) ranged in age from 32 to 97 years (mean 65) and the 22 women (41%) from 21 to 93 years (mean 62) (Fig. 1). Thirty-eight (70%) were white and 16 (30%) were black. Of the 54 patients, 46 (85%) had clinical evidence of congestive heart failure (CHF) at some time. The duration of CHF was discernible in 39 of the 46 patients and ranged from 1 to 108 months (mean 18): for ≤12 months in 25 patients (64%), from >12 to 24 months in 6 patients (15%), from >24 to 36 months in 3 patients (8%), and from 60 to 108 months (mean 82) in 5 patients (13%). The duration of CHF in 18 women ranged from 1 to 72 months (mean 18) and in 25 men from 2 to 108 months (mean 22). Each of the 8 patients (15%) without clinical evidence of CHF died suddenly and unexpectedly: in 3 sudden death was the first evidence of amyloidosis, 2 had familial amyloidosis, 2 had multiple myeloma, and 1 clinically had presumed alcoholic cirrhosis (which at necropsy actually was massive hepatic amyloid infiltration). The 8 patients dying suddenly without ever having clinical evidence of CHF ranged in age from 21 to 88 years (mean 56) and the 46 patients with CHF from 32 to 97 years (mean 65). Chest pain was present at some time during amyloid illness in 8 patients (15%), 4 of whom were considered to have angina pectoris.[2,3] Of the 4 patients (aged

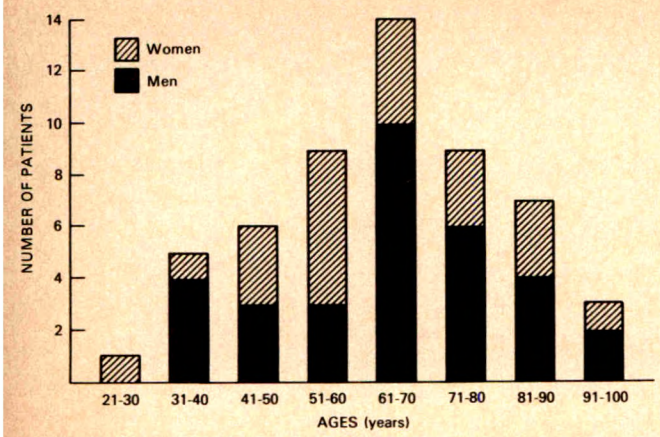

FIGURE 1. Age and sex distribution in the 54 necropsy patients with cardiac amyloidosis extensive enough to cause cardiac dysfunction.

67 to 89 years [mean 80]) with angina, 2 at necropsy had 1 or more of the 4 major (right, left main, left anterior descending, and left circumflex) epicardial coronary arteries narrowed 76 to 100% in cross-sectional area by atherosclerotic plaques.

Seven patients (13%) had histories of illnesses considered compatible with acute myocardial infarction that healed, but electrocardiographic and enzymatic documentation of myocardial necrosis at the time was unavailable. Grossly visible left ventricular scars, however, were absent at necropsy in all 7 patients, indicating that the histories of acute myocardial infarction in them were fallacious.

Four patients (7%) had 1 or more episodes of syncope. One patient was among the 4 with familial amyloidosis with peripheral neuropathy and postural hypotension. The mechanism of the syncope in the other 3 patients was not determined.

Systemic arterial pressure recordings during the last 3 months of life were available in 43 (80%) of the 54 patients. Although 24 (44%) of the 54 patients had a history of "hypertension," in none of the 43 patients (including the 24) with indirect blood pressure recordings available during the last 3 months of life was the systolic pressure >130 mm Hg or the diastolic pressure >90 mm Hg. The range of systolic arterial pressures during the last 3 months of life was 80 to 130 mm Hg (average 102) and of diastolic pressures 40 to 90 mm Hg (average 66).

TABLE I Cardiac Amyloid Causing Cardiac Dysfunction: Electrocardiographic Observations in 40 Patients*

Abnormality [No. (%)]	No. of Patients (%)
1. Low voltage (QRS ≤15 mm in I + II + III)	25 (63)
2. Myocardial infarct pattern	33 (83)
Anterior = 26 (79)	
Posterior = 2 (6)	
Both = 5 (15)	
3. Abnormal QRS axis	29 (73)
Right (+111 to +210°) = 6 (21)	
Left (−30 to −90°) = 23 (79)	
4. Arrhythmias	29 (73)
Atrial fibrillation = 9 (31)	
Atrial or junctional tachycardia = 10 (34)	
Ventricular premature complexes = 21 (72)	
5. Heart block	18 (45)
P-R interval >0.20 = 9 (50)	
2° AV block = 4 (22)	
3° AV block = 5 (28)	
6. Complete bundle branch block (QRS ≥0.12)	7 (18)
Right = 5	
Left = 2	

AV = atrioventricular.
* Numbers in parentheses represent percentages.

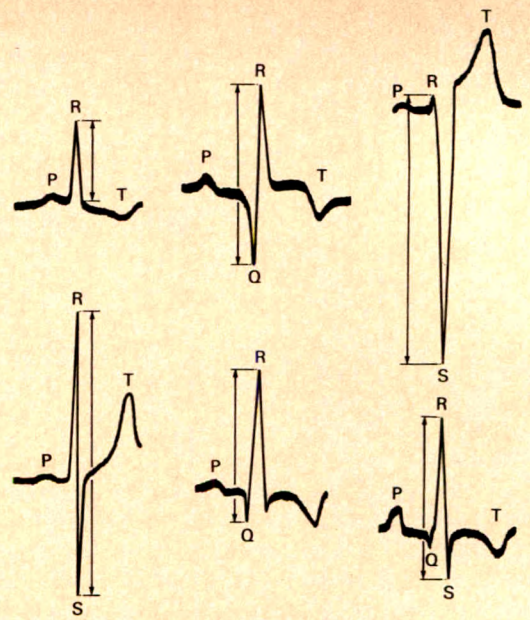

FIGURE 2. Various QRS complexes showing how each was measured.

The cardiac silhouette was enlarged on chest roentgenogram during the last few months of life in 39 (72%) of 54 patients. In several patients, however, earlier radiographs had shown the cardiac silhouette to be of normal size.

Adequate information on precordial examinations during the last few months of life was available in 44 of the 54 patients, 36 (82%) of whom had precordial murmurs. They were of a blowing type and consistent with mitral or tricuspid regurgitation, or both, in 35 (97%): grade 1 to 2/6 in 26, grade 3/6 in 7, and grade 4/6 in 2 patients. In addition, 1 patient had a murmur typical of valvular aortic stenosis (grade 3/6), which was confirmed to be present and was the type typically observed in the elderly.[4] At least 22 patients had third heart sounds (S_3) and at least 8 patients had fourth heart sounds (S_4).

Reports of 1 or more electrocardiograms recorded in the last 6 months of life were available in 40 patients, and all were abnormal (Table I). Of the 40 patients, electrocardiograms, recorded 0 to 160 days (mean 41) before death, were available for reexamination in 30 (Table II). In each of these 30 patients (15 women and 15 men), the QRS amplitude in all 12 leads was measured (Fig. 2). The total 12-lead QRS amplitude in the 15 men (mean age 52 years) ranged from 60 to 197 mm (mean 99) (10 mm = 1 mV) and in the 15 women (mean age 65 years) from 58 to 199 mm (mean 109). The heart weights in the 15 men ranged from 410 to 750 g (mean 570), and in the 15 women from 370 to 900 g (mean (494) ($p < 0.01$). Some electrocardiograms are illustrated in Figures 3 to 6.

Information regarding digitalis therapy was available in 40 patients, and 31 of them received this drug. At least 12 (39%) of the 31 patients developed physical or electrical signs, or both, considered typical of digitalis toxicity.

M-mode echocardiograms were performed in the last few months of life in 11 patients. The findings are summarized in Table III and illustrated in Figures 6 and 7.

Cardiac catheterization was performed in the last few months of life in 10 patients (19%), and the findings are summarized in Table IV.

Of the 54 patients, the amyloidosis was primary in 42 (78%), associated with multiple myeloma in 7 (13%), and familial in 5 (9%). None of the 54 patients had "secondary" amyloidosis.

Diagnosis of amyloidosis was established by biopsy of noncardiac organs or tissues during life in 18 patients (33%), including 5 of the 8 patients without and in 13 (28%) of the 46 patients with chronic CHF. Of the 21 patients having undergone biopsy of noncardiac organs or tissues, findings in 18 were positive for amyloid: rectum, 6 of 6; gingiva, 3 of 4; liver, 3 of 3; tongue, 2 of 3; kidney, 1 of 2; and each of prostate gland, thyroid gland, and lymph node, 1 of 1. In addition, endomyocardial biopsy of the right ventricular aspect of the ventricular septum was performed in 1 patient, but amyloid was not observed on histologic examination.

Of the 46 patients with chronic CHF, biopsy of a noncardiac organ or tissue was performed in 10 and all findings were positive for amyloid. In addition to these 10 patients, amyloidosis was considered the most likely cause of chronic CHF in 9 other patients. The cause of chronic CHF was never established during life in the remaining 27 patients (59%). Of the 11 patients having undergone M-mode echocardiography, the maximal thickness of the ventricular septum was greater than that of the left ventricular free wall in 5, and as a consequence hypertrophic cardiomyopathy was the suspected diagnosis clinically in each of them (Fig. 8 and 9). One of these 5 patients also had undergone cardiac catheterization, and hypertrophic cardiomyopathy continued to be the most likely clinical cardiac diagnosis after that procedure. Inability to differentiate clinically between constrictive pericardial disease and restrictive cardiomyopathy led to thoracotomy in 3 patients. At operation, all 3 had normal visceral and parietal pericardia and normal amounts of pericardial fluid. Each of these 3 patients died within 5 days of thoracotomy.

Eight patients had transient episodes of chest pain. In 4 the pain was consistent with angina pectoris, and a diagnosis of coronary heart disease was made in each. At necropsy, however, only 2 of the 4 patients had significant narrowing of an epicardial coronary artery by atherosclerotic plaque. Of the 4 patients with chest pain not consistent with myocardial ischemia, 1 had significant narrowing of 1 or more epicardial coronary arteries by atherosclerotic plaques. One of the latter 4 patients was 1 of the 3 with clinical pericardial constriction syndrome. The cause of chest pain in the other 2 was unclear. All 8 patients with chest pain had chronic CHF, and 2 had a history of acute myocardial infarction in the remote past. All 8 patients had luminal narrowing of many intramural coronary arteries by amyloid deposits.

Morphologic findings: The hearts in all 54 patients were examined initially by 1 of us (WCR), and 40 were reexamined together by both of us. Heart weights, available in 50 of the 54 patients, ranged from 300 to 900 g (mean 554). Of the 22 women, heart weights, available in 19, ranged from 300 to 900 g (mean 484) and 17 (89%) of the 19 weighed >350 g (a weight considered the upper limit of normal in adult women). Of the 32 men, heart weights (available in 31) ranged from 410 to 900 g (mean 596) and all 31 weighed >400 g (a weight considered the upper limit of normal in men).

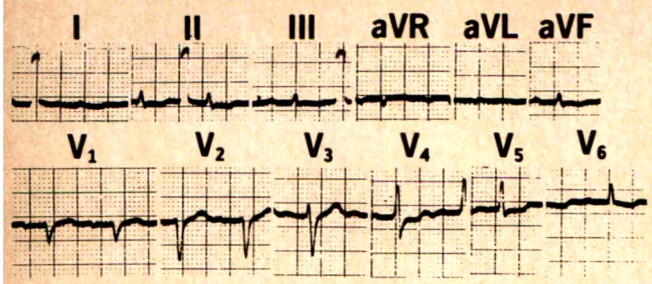

FIGURE 3. Electrocardiogram in a 55-year-old man (A56-81) recorded 23 days before death. The patient never had congestive heart failure. The heart weighed 480 g. The total 12-lead QRS voltage is only 60 mm. R waves are absent in leads V_1 and V_2 and small in V_3.

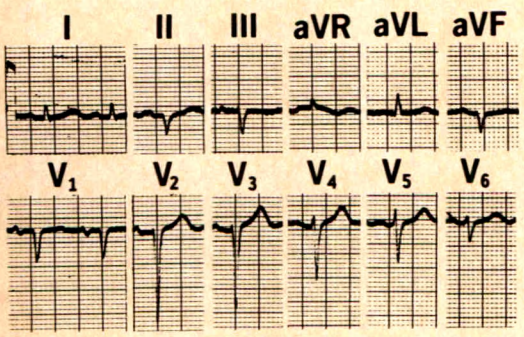

FIGURE 4. Electrocardiogram in a 55-year-old man (A61-190) recorded 2 days before death. The heart weighed 535 g and the total 12-lead QRS voltage is 85 mm. The voltage is decreased. The axis is leftward, Q waves are present in leads II, III, and aVF, and R waves are absent or small in the precordial leads.

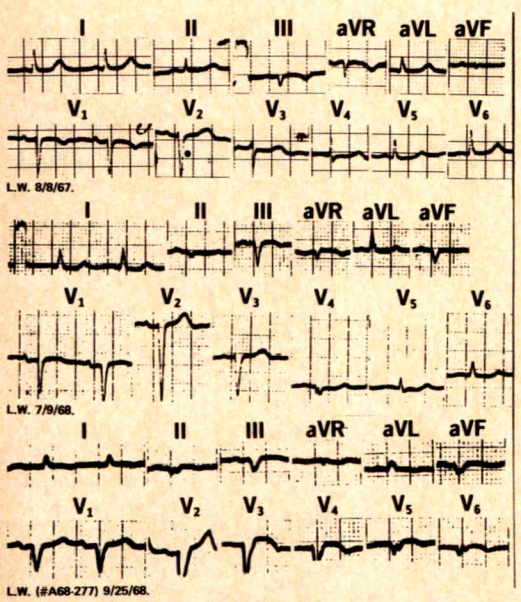

FIGURE 5. Electrocardiograms recorded over a 13-month period in a 53-year-old woman (A68-277) who had congestive heart failure for 5 months. The heart weighed 370 g. She died October 9, 1968. She had low voltage, left axis deviation, and absent R waves in the precordium. On the final electrocardiogram, the total 12-lead QRS voltage is 58 mm.

The hearts in 53 of the 54 patients were firm and rubbery, and this noncompliant consistency of the walls of all 4 cardiac chambers usually allowed the diagnosis of cardiac amyloidosis to be made immediately at necropsy without knowledge of clinical findings (Fig. 7 to 10). Both atria in all 54 patients on gross inspection were dilated, usually to a moderate degree. In contrast, the cardiac ventricles on gross inspection were of normal size in 43 patients (80%) and dilated in 11 (20%). The patients with dilated ventricles usually had other conditions that probably caused the dilatation: coronary heart disease

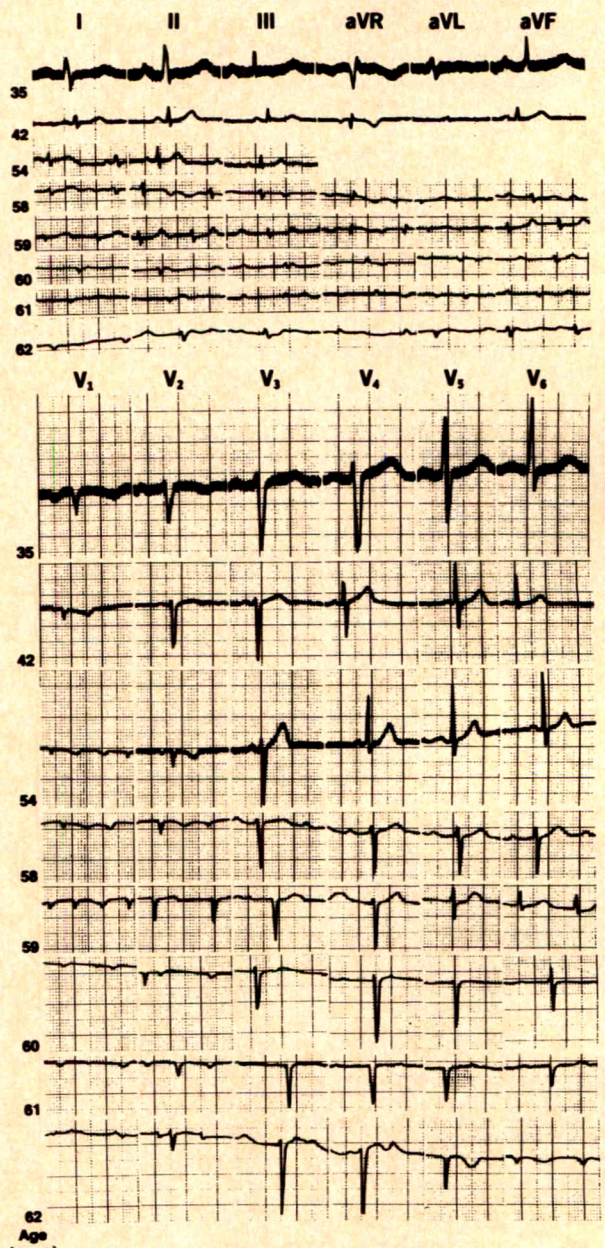

FIGURE 6. Electrocardiograms over a 27-year period in a 62-year-old man (GT 74A-259) who had congestive heart failure for 96 months and, at necropsy, a heart weighing 470 g. The QRS voltage progressively diminished, the axis changed, and R waves disappeared from the precordial leads. While taking digitalis, he developed atrial tachycardia with 2:1 block. The total 12-lead QRS voltage on the final electrocardiogram recorded 9 days before death was 79 mm.

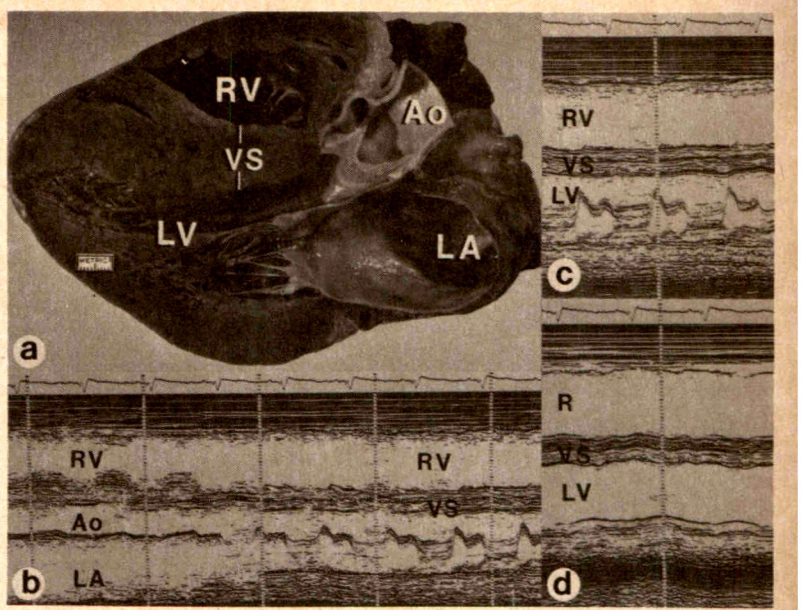

FIGURE 7. Cardiac amyloid with anasarca and pulmonary emboli. Longitudinal view of heart, weighing 545 g, in a 46-year-old man (A81-6) who had been well until 25 months before death, when parathesias and shoulder pain were noted. During his last 3 months he had severe congestive heart failure. When hospitalized 8 days before death, he had anasarca and third and fourth cardiac sounds. Electrocardiography showed a left atrial abnormality, right axis deviation, and poor R-wave progression over the precordium. Echocardiograms (**b, c, and d**) disclosed the ventricular septum (VS) and left ventricular (LV) free walls to be of similar thickness and each moved hardly at all. Both the left atrium (LA) and right ventricle (RV) were dilated. The pressures in mm Hg were: mean pulmonary artery wedge pressure, 27; pulmonary artery, 60/30; RV, 60/16; left ventricle, 90/26; and brachial artery, 90/60. He died from ventricular tachyarrhythmias. The heart in a longitudinal axis view is shown in **a**. The myocardium had the typical firm, rubbery appearance of extensive amyloidosis. Several pulmonary emboli may be the explanation of the right ventricular dilatation. Ao = aorta.

with left ventricular transmural scarring or chronic lung disease. The maximal thickness of the ventricular septum was identical or nearly so to the maximal thickness of the left ventricular free wall in 50 patients (93%); in the other 4 (7%) the septum was >1.3 times thicker than the free wall.

By gross examination, amyloid deposits (focal, tan, and waxy-appearing) were observed (and confirmed histologically) in the mural endocardium of 1 or both atria in all 54 patients and in valvular endocardium of 1 or more cardiac valves in 46 patients (85%) (Fig. 11): in the leaflets of the tricuspid valve in 45 patients (83%), the mitral valve in 43 patients (80%), the pulmonic valve in 29 patients (54%), and the aortic valve in 29 patients (54%). In 27 patients (50%), amyloid deposits were observed grossly in the leaflets of all 4 cardiac valves.

Focal transmural left ventricular lesions were observed grossly in 9 patients (17%) (Fig. 8); on histologic examination the lesions consisted entirely of fibrous tissue in 7 patients (13%) and of amyloid deposits in 2 (4%).

At least 3 histologic sections of heart were examined in each patient. In every patient, at least 1 section of left ventricular wall and at least 1 section of atrial wall were examined. Amyloid deposits, readily identified on hematoxylin-eosin stains, were confirmed by either congo red or crystal violet stains or both. In the chamber walls, the amyloid deposits were located in (1) interstitium, that is, between myocardial fibers, not within them in all but 1 patient,[4] (2) endocardium, often of all 4 chambers but always of 1 or both atria in all patients, and (3) within the walls of several intramural coronary arteries in all patients (Fig. 12). Additionally, amyloid deposits often were found in the lumina of some intramural coronary arteries, causing severe (>75% in cross-sectional area) narrowing of some lumina. Despite numerous sections of the major epicardial coronary arteries, no amyloid deposits were observed. At least 1 and usually multiple cardiac valves contained amyloid deposits, but none were judged to have deposits of sufficient quantity to cause valvular dysfunction. In several patients in whom histologic sections included coronary sinus, amyloid deposits were visible histologically in the wall of this structure.

In all 54 patients, amyloid deposits were observed in 1 or more other body organs. No patient had amyloid limited to the heart.

* Measurements in mm Hg.

Thrombi were observed grossly in 1 or more of the 4 cardiac chambers in 14 (26%) of the 54 patients: in 1 chamber only in 8 patients, in 2 chambers in 3 patients, in 3 chambers in 1 patient, and in all 4 chambers in 1 patient. Of the 22 cardiac chambers that contained thrombi (mainly fibrin in all) in the 14 patients, the right atrial appendage contained thrombi in 10 patients (isolated in 5); the left atrial appendage contained thrombi in 7 patients (isolated in 2); the right ventricle con-

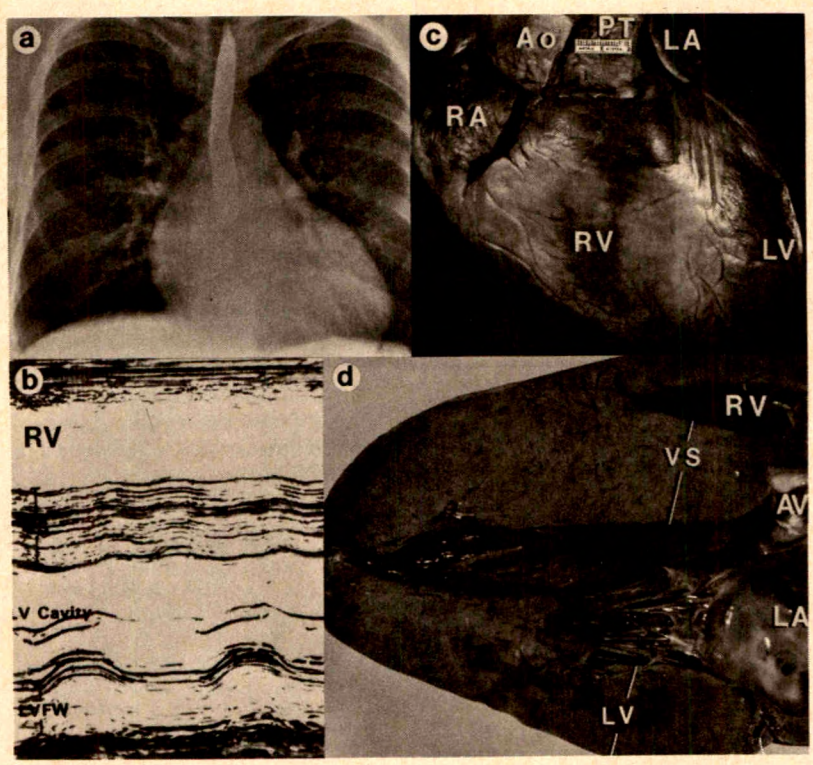

FIGURE 8. Cardiac amyloidosis simulating hypertrophic cardiomyopathy. Chest radiograph (**a**), M-mode echocardiogram just caudal to the tips of the mitral leaflets (**b**), exterior view of heart (**c**), and longitudinal axis view of heart (**d**) in a 46-year-old man (A79-25) who noted dyspnea while walking 24 months before death. M-mode echocardiography 1 month later disclosed the ventricular septum (VS) to be 1.7 times thicker than the left ventricular free wall (LVFW). The anterior mitral leaflet moved anteriorly during ventricular systole. The left atrial cavity was 30 mm in diameter. The pressures in mm Hg were: mean pulmonary arterial wedge, 5; pulmonary artery, 17/6; right ventricle (RV), 17/3; left ventricle (LV), 130/11; and aorta (Ao), 115/70. Clinically, the patient at that time was considered to have hypertrophic cardiomyopathy. Nine months before death, he had transient sudden left-sided weakness with slurred speech, worsened dyspnea, transient chest pain, and the carpal-tunnel syndrome was noted. Now the mean pulmonary arterial wedge pressure was 23; right ventricular pressure, 47/7; LV, 95/25; and Ao, 95/65 mm Hg. Echocardiogram now showed the ventricular septum to be 2.0 cm and the LVFW 1.5 cm; SAM now was absent. The left atrium (LA) now was 55 mm in diameter. A third catheterization performed 10 days before death showed the mean pulmonary wedge pressure to be 32 and that in the RV 65/11 mm Hg. The cardiac index was 1.4 liters/min/m^2. The heart was enlarged (**a**). M-mode echocardiogram (**b**) now showed the VS to be 2.6 cm and the LVFW 1.5 cm thick. Cardiac amyloidosis was never diagnosed clinically. At necropsy, the heart weighed 780 g. In addition to the usual interstitial myocardial amyloid, large deposits of amyloid were visible grossly on the LVFW (**d**). The VS is thicker than the free wall. The epicardial coronary arteries were virtually free of atherosclerotic plaques. AV = aortic valve; PT = pulmonary trunk; RA = right atrium; SAM = systolic anterior motion of the anterior mitral leaflet.

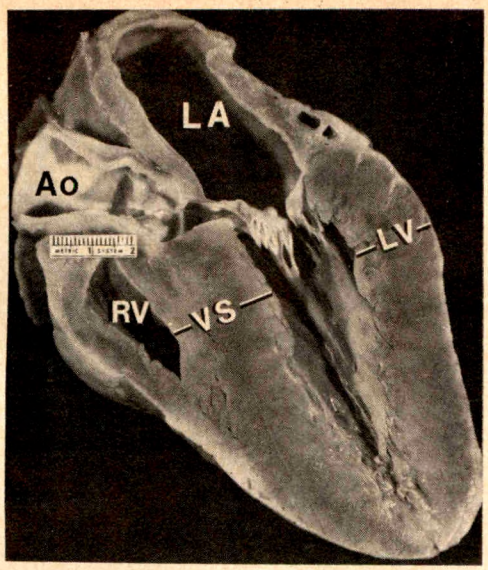

FIGURE 9. Cardiac amyloidosis simulating hypertrophic cardiomyopathy. Long-axis view of heart in a 55-year-old woman (WMC#A79-24) who had been well until 6 months before death when she developed periorbital purpura, pedal edema, and right-arm pain. When syncope occurred a month later, she was hospitalized and found to have multiple myeloma. Electrocardiography disclosed both atrial and ventricular arrhythmias and electrophysiologic studies disclosed distal H-V block. She never had congestive heart failure. On the day of death at home she fainted and soon thereafter had fatal cardiac arrest. The heart weighed 430 g and it had the typical amyloid consistency. A long-axis view is shown. The ventricular septum (VS) is thicker than the left ventricular (LV) free wall. The left atrium (LA) is dilated. Ao = aorta; RV = right ventricular cavity.

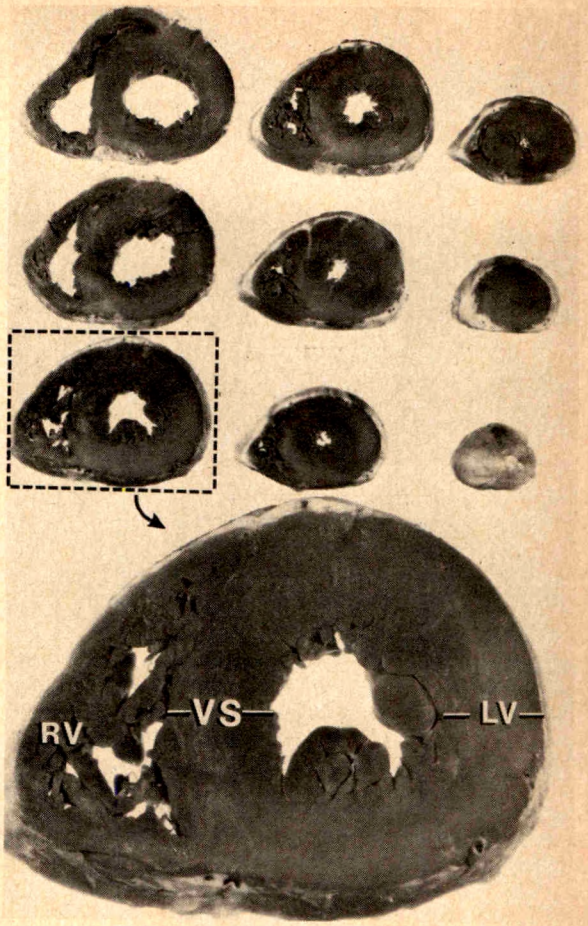

FIGURE 10. Massive ventricular amyloid deposits. Transverse cuts of the ventricles in the 49-year-old man (NNMC#A80-15), described in detail in Figure 3. This uniform appearance of the ventricular walls is the most common finding in extensive cardiac amyloidosis. LV = left ventricle; RV = right ventricle; VS = ventricular septum.

tained thrombi in 2 patients (none isolated), and the left ventricle contained thrombi in 3 patients (isolated in 2). Thus, of the 22 chambers with thrombi, 17 were atrial appendages and 5 were ventricles. None of the 5 ventricles containing thrombi appeared dilated by gross inspection. Of the 14 patients with intracardiac thrombi, 13 had clinical evidence of CHF and 1 died suddenly without evidence at any time of CHF: 2 (of 13) had chronic atrial fibrillation; 2 had clinical evidence of either pulmonary or systemic emboli, and 5 had severe narrowing of 1 or more epicardial cardiac arteries by either atherosclerotic plaque (4 patients) or fibrin-platelet embolus (1 patient). The latter patient was reported on previously.[2]

In addition to the extensive cardiac amyloid deposits, 8 patients (15%) had narrowing >75% in cross-sectional area by atherosclerotic plaques of 1 or more of the 4 major (right, left main, left anterior descending, and left circumflex) epicardial coronary arteries: in 5 patients, 3 of the 4 major arteries were so narrowed; in 1 patient 2 arteries, and in 2 patients 1 artery. The ages of these 8 patients ranged from 65 to 96 years (mean 78); 6 were men and 2 were women. Four had had periodic chest pain, considered angina pectoris in 2. One patient died suddenly and unexpectedly. At necropsy none had foci of myocardial necrosis, but 4 had healed transmural left ventricular infarcts, all of which had been clinically silent.

Calcific deposits were present in the mitral anulus in 7 patients (13%) and in 1 or more aortic valve cusps in 9 patients (17%). In 6 patients, the calcific deposits were present in both mitral anulus and in aortic valve cusps, in 3 patients they were limited to aortic valve cusps, and in 1 patient they were limited to mitral anulus. In 2 of the 9 patients with aortic valve calcium, the deposits appeared extensive enough to cause narrowing of the aortic valve orifice. In none of the 7 patients with mitral anulus calcium did the calcific deposits appear to cause clinically significant mitral dysfunction. All 10 patients (19%) with either mitral anular or aortic valve cuspal calcific deposits, or both, had calcific deposits in 1 or more of the 4 major epicardial coronary arteries, and in each patient they were within atherosclerotic plaques.

Discussion

Patients with cardiac amyloid deposits may readily be separated into 2 major groups: (1) those with amyloid deposits too small to produce cardiac dysfunction, and (2) those with amyloid deposits large enough to produce cardiac dysfunction which eventually is fatal. The finding of minute cardiac amyloid deposits in the heart in elderly persons at necropsy is common,[5–13] but patients with minute cardiac deposits, whether they be young or old, are not included in the present analysis. Each of our 54 patients had heavy cardiac amyloid deposits that caused fatal cardiac dysfunction. All but 1 had firm, rubbery ventricular and usually atrial walls with amyloid deposits in the interstitium (between myocardial cells) of the walls of all 4 chambers, in mural and usually in valvular endocardium, and in the in-

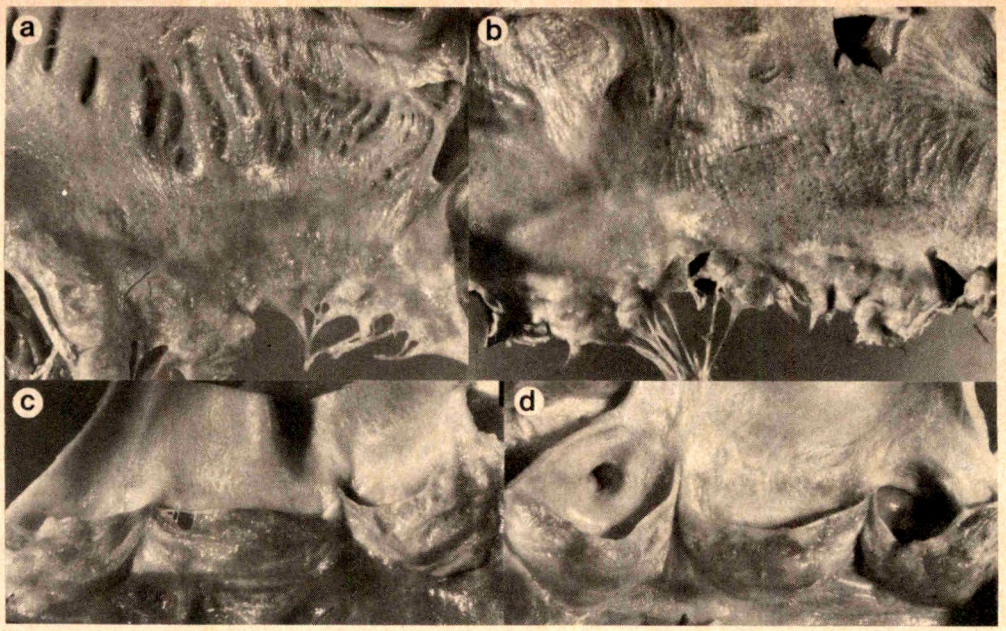

FIGURE 11. Endocardial amyloidosis. Opened right atrium and tricuspid valve (**a**), opened left atrium and mitral valve (**b**), opened pulmonic valve and pulmonary trunk (**c**), and opened aortic valve and aorta (**d**). The mural endocardium of each chamber and the cusps of all 4 cardiac valves contain amyloid deposits. The ventricular myocardium (shown in Figure 4) also contained massive quantities of amyloid, as did the pulmonary trunk. This 49-year-old man (NNMC#A80-15) had been well, but an automobile accident prompted an examination 10 months before death. Both pedal edema and hepatomegaly were found, the blood pressure was elevated (160/100 mm Hg), the heart was enlarged (cardiothoracic ratio 0.55), and electrocardiogram disclosed no R waves in leads V_1–V_3, nonspecific ST-T wave abnormalities, and low voltage. Echocardiogram was normal. Hepatic biopsy yielded amyloid. He remained asymptomatic until 4 months before death, when extensive subcutaneous edema appeared and pericardial effusion (700 ml) was found. The systemic blood pressure was then 120/80 mm Hg. His condition progressively worsened thereafter. He became acutely dyspneic at home and died.

FIGURE 12. Location of amyloid in myocardium (**a** and **b**), intramural coronary artery (**c**) and epicardial nerve (**d**). **a,** massive interstitial myocardial amyloid observed in a longitudinal section in an 89-year-old man (A69-259) with chronic congestive heart failure (CHF) and a heart weighing 520 g. In this section, more amyloid than myocardial fibers are present. **b,** massive interstitial myocardial amyloid observed in cross section in a 68-year-old man (H-A76-143) who had CHF for 36 months. **c,** amyloid occluding the lumens of intramural coronary arteries in a 67-year-old man (A69-187) with chronic CHF and a heart weighing 550 g. **d,** amyloid in epicardial nerves in a 74-year-old man (A58-190) who died suddenly from familial amyloidosis and had a heart weighing 700 g. (Hematoxylin-eosin stain [**a**] ×25 and [**d**] ×100; Movat stain [**b**] ×100; Masson stain [**c**] ×39, all reduced 25%.)

tramural coronary arteries. The 1 patient without interstitial myocardial amyloid had amyloid filling the lumina of most intramural coronary arteries.[3] Additionally, several patients had amyloid in the epicardium but never in the walls or lumina of the major epicardial coronary arteries. All our 54 patients with cardiac amyloid had amyloid deposits in 1 or more noncardiac body organs. We suspect that cardiac amyloid severe enough to cause clinical evidence of cardiac dysfunction is never limited exclusively to the heart.

Although a diagnosis of cardiac amyloidosis was established clinically in less than half of our 54 patients, most were studied clinically before echocardiography and radionuclide angiography became commonly performed procedures. Echocardiography is now often one of the first clues to the diagnosis of cardiac amyloidosis,[14–19] and myocardial technetium-99m pyrophosphate scintigraphy may be diagnostic of this condition.[20–23] Thus, cardiac amyloidosis severe enough to cause cardiac dysfunction almost surely will be suspected hereafter in a majority rather than in a minority of patients. Clinically, diagnosis of cardiac amyloidosis should be suspected in an older patient with evidence of CHF, poorly responsive and/or particularly sensitive to digitalis, unassociated with chest pain or systemic hypertension, and in the presence of cardiomegaly by chest radiograph but low voltage by electrocardiogram. The echocardiogram, rather than showing dilatation of the left ventricle, shows this chamber to be of normal or near-normal size and the ventricular walls to move poorly, and these findings can be confirmed by hemodynamic and angiographic studies.[24–27] Biopsy of either noncardiac or cardiac[28] tissue is required for absolute diagnosis.

Severe cardiac amyloidosis is 1 of the causes of spontaneous cure of systemic hypertension. Although nearly half of our 54 patients had had either a history of systemic hypertension or recordings of elevated systemic arterial pressures, or both, all had systolic systemic pressures ≤130 mm Hg and diastolic systemic pressures ≤90 mm Hg in the last 3 months of life. The average recorded peak systolic arterial pressure in the last 3 months of life in our patients was 102 mm Hg and the diastolic pressure was 70 mm Hg. Thus, if the systemic arterial pressure is elevated in a patient with CHF, the chance that the CHF is the result of cardiac amyloidosis is minimal. Additionally, none of our patients had evidence of left ventricular hypertrophy by electrocardiogram in their final 3 months, although several had had left ventricular hypertrophy by electrocardiogram >1 year earlier.

The length of time necessary to develop cardiac amyloid deposits extensive enough to cause cardiac dysfunction is uncertain. One clue to the amount of time required can be gained by study of the systemic arterial pressures over several years. We have now observed several patients with systolic systemic pressures in the vicinity of 180 mm Hg; during a period of 4 to 5 years this pressure gradually decreased to about 100 mm Hg without use of antihypertensive agents. Thus, a gradual but spontaneous decrease in systemic arterial pressure also might be a clue to the development of cardiac amyloidosis.

Cardiac amyloidosis needs to be added to the list of great cardiac masqueraders. Initially, it was cardiovascular syphilis that was stated to frequently simulate other cardiac conditions. In recent years, hypertrophic cardiomyopathy has become the most prominent masquerader. The QRS and T-wave changes on the electrocardiogram in cardiac amyloidosis are similar to those produced by healed myocardial infarction secondary to coronary atherosclerosis. The presence of a nondilated left ventricle and the presence of a ventricular septum thicker than the left ventricular free wall by echocardiogram has suggested the presence of hypertrophic cardiomyopathy. Five of our 11 patients with echocardiograms were suspected of having hypertrophic cardiomyopathy because of the combination of these findings. Simulation of cardiac amyloidosis clinically to pericardial constriction has long been recognized.[1,24–27] Three of our 54 patients underwent thoracotomy because of suspected pericardial constriction. Cardiac amyloidosis may present as pericardial tamponade.[29] Its delayed left ventricular filling may simulate mitral stenosis on rare occasions.[30]

Although amyloid deposits are always more extensive in "working" than in "conducting" myocardium,[1,31,32] arrhythmias and conduction disturbances are common (Table I). Some of these disturbances, however, may be the result of aging rather than the result of extensive cardiac amyloidosis.[13,33] In our patients, left-axis deviation (58%), atrial fibrillation (23%), and bundle branch block (18%) were common, but these also are relatively common in elderly patients without cardiac amyloidosis.[13,33] The frequency of low voltage (63%) and a healed myocardial infarction pattern (83%), however, was striking in our patients, and each of these should raise the possibility of cardiac amyloidosis in a patient with CHF of unclear cause.

This report provides for the first time measurements of QRS voltages in each of the 12 leads of an electrocardiogram in patients with cardiac amyloidosis. Simonson[34] provided data on the upper and lower limits of amplitude of the QRS complexes in each of the 12 leads in normal men and women aged 20 to 59 years. (The mean for normal subjects is not available.) The upper and lower limits of normal for men aged 50 to 59 years were 277 and 36 mm and for women 248 and 27 mm, respectively. The upper and lower limits of amplitude in all leads in 30 of our 54 patients (Table II) were 199 and 58 mm, respectively, and averaged 104 mm. For our 15 women from whom the data were available, the total 12-lead QRS voltage ranged from 58 to 199 mm (mean 109) and for our 15 men from 60 to 197 mm (mean 99).

In comparison, Siegel and Roberts[35] determined the total 12-lead QRS voltage in 50 patients (aged 16 to 65 years) with severe and fatal isolated aortic valve stenosis. The upper and lower limits of amplitude in all 12 leads in their 50 patients were 417 and 144 mm, respectively, and averaged 260 mm. In their 14 women with aortic stenosis, the total 12-lead QRS voltage averaged 277 mm and in their 36 men, 249 mm. The average heart weight of their 14 women with aortic stenosis was 521 g, and the heart weight in our 15 women with severe cardiac amyloidosis and available total 12-lead

QRS voltage was 494 g. The difference, however, in average total 12-lead QRS voltage (277 mm versus 109 mm) was a factor of 2.5 times. The mean heart weight of the 36 men with aortic stenosis studied by Siegel and Roberts[35] was 639 g and that of our 15 men with fatal cardiac amyloidosis and available total 12-lead QRS voltage was 570 g. The average total 12-lead QRS voltage in the 36 men with aortic stenosis, however, was 249 mm compared with only 99 mm in our 15 men with fatal cardiac amyloid, again a 2.5-fold difference. Thus, although the sum of the QRS voltage in leads I, II, and III may not fulfill criteria of "low voltage," that is, ≤15 mm, the total QRS voltage in all 12 leads in severe cardiac amyloidosis is usually considerably lower than normal, and particularly small in proportion to the weight of the heart.

Cardiac Thrombosis and Thromboembolism in Chronic Chagas' Heart Disease

J. SAMUEL M. OLIVEIRA, MD, PhD, ROSALY R. CORREA DE ARAUJO, MD, MARCOS A. NAVARRO, MD, and GERSON MUCCILLO, PhD

A retrospective study of Chagas' heart disease was carried out by a review of 1,345 autopsy reports, with special reference to cardiac thrombus and thromboembolic phenomena. The incidence of cardiac thrombus was higher in cases of heart failure (36%) than in cases of sudden death (15%), higher in heavier hearts, and unrelated to age or sex. The left- and right-sided cardiac chambers were equally affected by thrombus. Endocarditis and blood stasis were considered important factors in the pathogenesis of cardiac thrombus. Thromboembolic phenomena were more common in the systemic circulation but caused relatively more deaths by pulmonary embolism. Fourteen percent of patients with thromboembolic phenomena died from them. Patients with multiple thromboembolic phenomena had a higher risk of death from embolism. Cardiac thrombosis or thromboembolic phenomena, or both, were present in 44% of the cases studied. Prophylactic measures should be taken for these important complications of Chagas' heart disease.

The difficulties involved in the prevention and treatment of thromboembolic phenomena are well known, especially in terms of proper diagnosis of causative factors and consequences, both in the pulmonary[1] and systemic[2] circulation. Thromboembolic episodes are of particular importance in regions where Chagas' disease is endemic. In this respect, it is important to point out that Chagas' heart disease was once labelled an "emboligenic cardiomyopathy."[3] Pertinent studies in such regions, however, are limited in number and were mainly conducted in small samples.[4–6] The one exception, a detailed study[7] of 208 cases with special emphasis on thromboembolic phenomena and their consequences, was based on selected material (Chagasic patients with heart failure).

Large numbers of patients with Chagas' heart disease die suddenly, even though they never had heart failure and, at times, never had any previous symptoms.[8] This form of Chagas' heart disease is familiar mainly to pathologists. A detailed anatomopathologic study of sudden death[9] did not completely explore thromboembolic phenomena. The present study of 1,345 cases was carried out to clarify the sources and consequences of thromboembolic phenomena in Chagas' heart disease by comparing cases with and without heart failure, based on a retrospective examination of autopsy reports.

From the Department of Pathology, Medical School of Ribeirão Preto, and the Department of Geology, Physics, and Mathematics, Campus of Ribeirão Preto, University of São Paulo, Ribeirão Preto, State of São Paulo, Brazil. This investigation received financial assistance from the UNDP/World Bank/World Health Organization Special Program for Research and Training in Tropical Diseases (World Health Organization, Geneva, Switzerland). Manuscript received November 8, 1982; revised manuscript received March 30, 1983, accepted April 1, 1983.

Methods

Our routine procedure for examining hearts suspected to have Chagas' heart disease is to fill the heart with formalin after ligating the great vessels. After 24 to 48 hours of fixation, the heart is opened by a single cut from apex to the base. Collection of body fluids for the complement fixation test for Chagas' disease is also a routine procedure in all autopsied cases. The diagnosis of Chagas' heart disease was chiefly based on gross findings such as apical aneurysm, dilated pulmonary conus, cardiomegaly, right atrial appendage thrombosis, and "rosary bead" type epicarditis. The diagnosis was based on the presence of at least 2 of these lesions,[10] except for apical aneurysm, which in itself was sufficient.[11] Nevertheless, some cases required additional information such as clinical and serologic tests and histologic examination to confirm the diagnosis. Chronic myocarditis and fibrosis were present for all practical purposes in all cases of Chagas' heart disease.

Case selection: All autopsy reports of persons ≥10 years of age were examined (5,467 records). Patients reported as having Chagas' heart disease as the cause of death were preliminarily divided into 2 groups on the basis of the origin of

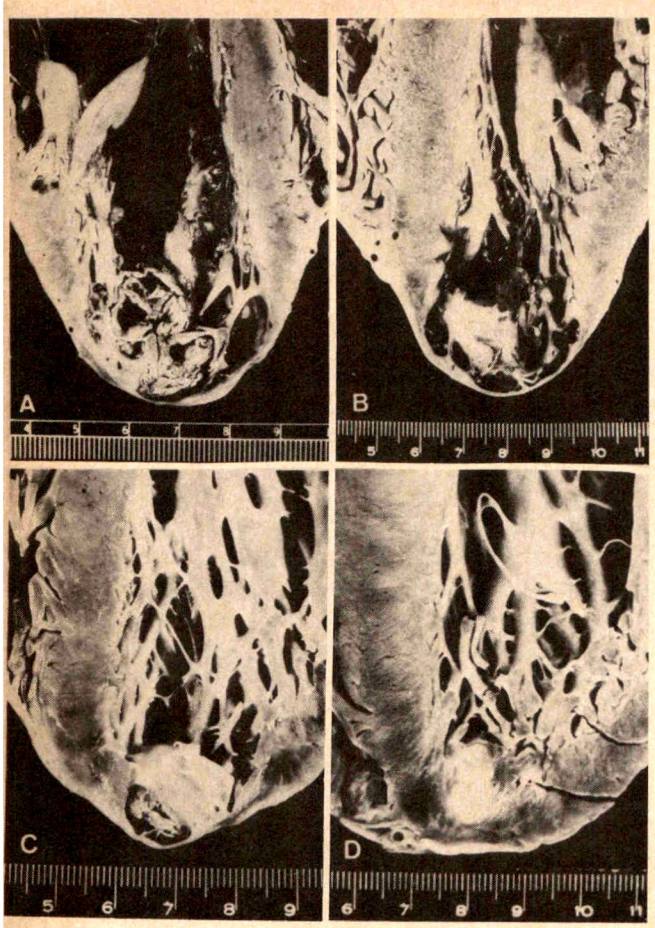

FIGURE 1. Cardiac thrombosis of the left apical region: with puriform softening (**A**) during different phases of organization (**B** and **C**) and completely hyalinized (**D**).

the autopsy request. Our department carries out postmortem examinations in (1) persons sent by hospitals at the request of a physician, and (2) persons who died a natural death without medical assistance, as required by law. Subjects in the first category are considered to have heart failure and subjects in the second to have sudden death (medically unattended, witnessed or unwitnessed).[12] All available information concerning these cases was then reexamined in order to exclude from the study: (1) cases included in the heart failure group without clinical or anatomic evidence of this condition, and cases in the sudden death group with evidence of heart failure; (2) cases presenting Chagas' heart disease in association with severe atherosclerosis, aortic aneurysms, or endocardial or valvular disease; and (3) cases with poorly documented evidence of Chagas' heart disease. On the basis of this second screening, approximately 20% of cases initially considered as Chagas' heart disease were excluded from the study, with a total of 1,345 cases remaining.

Although most of the autopsy reports were complete, occasionally some data such as age or heart weight were not available. These cases were excluded from the analysis of the feature not documented and for this reason there is a small variation in the total number of cases presented for each feature in the Results section.

Thromboembolic phenomena: The term *thromboembolic phenomena* is used in this report to designate infarction at different phases of evolution, including healing. It also designates recent embolism in cases where the interruption of blood flow was followed by death within a period not long enough to cause pathologic evidence of infarction in a given territory.

The search for deep vein thrombosis was not a routine procedure but was carried out in cases with pulmonary thromboembolic phenomena without right-sided heart chamber thrombosis. There were cases of pulmonary embolism with right-sided heart chamber thrombosis concomitant with vein thrombosis that was revealed either by clinical information or evident vein thrombosis; these cases are identified in the Results section.

Statistical procedure: The data were analyzed statistically by the chi-square test to assess independence between variables. Alpha values of <0.05 were considered significant. When appropriate, the comparison of 2 groups was performed by a test for difference between 2 proportions.

Results

The diagnosis of cardiac thrombosis is usually easily made at autopsy of Chagas' heart disease cases. Some thrombi, especially the apical ones, tend to hyalinize, and complete hyalinization of thrombi filling apical aneurysms may lead to an incorrect diagnosis of apical myocardial fibrosis as a primary lesion (Fig. 1). Ventricular thrombi occur almost exclusively in the apexes, and atrial thrombi in the atrial appendages.

Of 1,345 cases studied, 750 showed neither thromboembolic phenomena nor cardiac thrombosis. The remaining 595 cases (44%) presented the following features: thromboembolic phenomena with no thrombosis in the same side of the heart chambers (245 cases), only cardiac thrombosis (185 cases), or both thromboembolic phenomena and thrombosis in the same side of the heart (165 cases).

The incidence of cardiac thrombus did not differ by sex, was higher in cases of heart failure (Table I), and was unrelated to age (Table II). The left-sided chambers

TABLE I Cardiac Thrombosis in Cases of Chronic Chagas' Heart Disease, According to Sex and Mode of Death

Sex	Mode of Death	Thrombus		Without Thrombus	Total
		n	%		
Males	Heart failure	191	38	309	500
	Sudden death	65	16	349	414
Females	Heart failure	89	34	174	263
	Sudden death	24	14	144	168
Total	. . .	370	28	985	1,345

Male × female, chi-square = 1.41 (heart failure) and 0.18 (sudden death): both not significant. Sudden death × heart failure, chi-square = 75.98; significant. The proportion of thrombosis in cases of heart failure is significantly higher than in cases of sudden death ($z = 8.72$).

TABLE II Cardiac Thrombosis in Cases of Chronic Chagas' Heart Disease, According to Age

Age Range (yr)	Thrombus n	Thrombus %	Without Thrombus (n)	Total
<30	48	27	127	175
30–39	57	26	163	220
40–49	86	30	188	274
50–59	83	35	156	239
60–69	38	25	115	153
>70	18	26	51	69
Total	330	...	800	1,130

Chi-square = 7.32 (not significant).

of the heart were affected by thrombosis in 299 cases (the ventricle in 248 and the atrium in 51), whereas the right-sided chambers were affected in 280 cases (the ventricle in 86 and the atrium in 194). Table III shows the distribution of cardiac chambers affected by thrombosis. Heavy hearts were more affected by thrombosis than light hearts (Fig. 2).

The arterial beds most often affected by thromboembolic phenomena were lungs and kidneys, and the mortality rate due to such phenomena was mainly related to pulmonary and brain involvement (Table IV). The proportion of deaths directly caused by thromboembolic phenomena was significantly higher in cases with more than 1 arterial bed affected by thromboembolic phenomena: 25 of 247 cases with 1 arterial bed affected in contrast to 32 of 164 cases with more than 1 arterial bed affected (z = 2.70).

Discussion

The criteria used to initially separate heart failure and sudden death cases on the basis of hospital and police requests for autopsy were the basis of an initial screening that was subsequently refined using all available data as described in Methods. Less than 20% of the cases were eliminated during the second screening

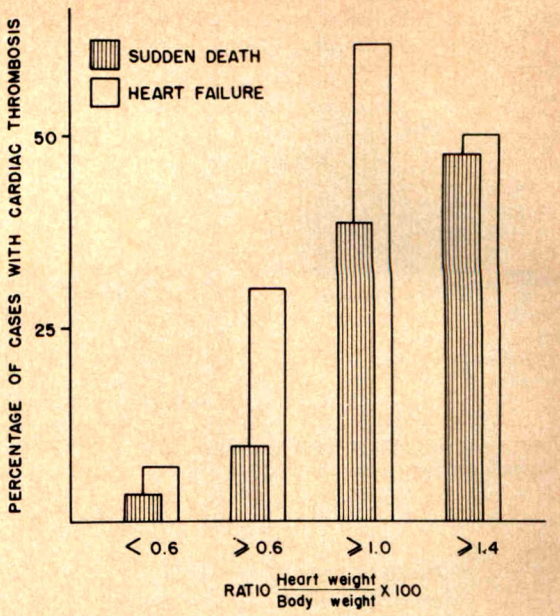

FIGURE 2. Cardiac thrombosis in cases of sudden death and heart failure according to the ratio heart weight/body weight ×100.

and none was transferred from 1 group to the other. Part of the reason for the effectiveness of the initial screening of the sudden death group was that most cases of poisoning and violent death were excluded by the police (that is, no autopsy was performed by our service) because these cases are required by law to be examined by a forensic pathologist. The few cases of poisoning or violent death that were encountered in our service were transferred to the forensic pathology service.

Cardiac thrombosis: The incidence of cardiac thrombosis in the 1,345 cases described here (27.3%) was lower than observed in other studies: 34% among 124 cases[6] and 76% among 208 cases.[7] These studies had been concerned exclusively with cases of heart failure. If we consider only the cases with heart failure in our

* Number of deaths due to thromboembolic phenomena. The total number of thromboembolic phenomena was 640 detected in 412 cases. Twenty cases showing both venous thrombosis and pulmonary embolism were not included in the data presented in this table.

sample, the incidence of cardiac thrombosis (36.3%) is lower than that obtained in 1[7] of the series cited, which was carried out in a different region of Brazil (State of Bahia). Regional differences are suspected to exist in relation to the manifestations of Chagas' disease,[13] but this matter is still controversial.[14]

There was no difference in incidence of cardiac thrombosis between sexes in our study. Usually the pathologic consequences of Chagas' disease are more common among males, as indicated, for example, by the higher incidence of megaesophagus[15] and apical aneurysm.[11] Studies on rats have demonstrated that androgen administration aggravates infection by *Trypanosoma cruzi*.[16]

It is known that thrombosis of ventricular aneurysms caused by myocardial infarction occurs regardless of the time of onset of the necrotic episode[17] and that the thromboembolic phenomena occurring in rheumatic heart disease are more frequent among the elderly.[18] Furthermore, Chagas' heart disease has its onset early in childhood[19] and is an evolving disease.[20] However, contrary to what was expected, our data show that there is no difference in the incidence of cardiac thrombosis.

The distribution of thrombosis among the different heart chambers (Table III) was similar to that expected for a series of 208 cases.[7] The frequency of the most affected chambers agreed with that obtained in the smaller series, although discrepancies occurred with respect to less frequent locations and combinations.[6,21,22] The apical region of the left ventricle is a critical region in the Chagasic heart, where aneurysms, thromboses, or both occur with high frequency. A cause-effect relationship has been suspected for thrombosis and apical aneurysm.[23]

Ventricular thromboses were not very voluminous and it is doubtful that they alone could have led to heart failure, as previously reported for another type of thrombotic involvement of the heart.[24]

The myocardial hypertrophy that occurs in Chagas' heart disease is usually accompanied by dilatation, especially in the right chambers.[25] Heavier hearts had a higher frequency of thrombosis (Fig. 2). Indeed, it has been reported that blood stasis alone is unlikely to cause thrombosis.[26] Parietal endocarditis has been reported in Chagas' heart disease,[27] and may be a promoting or contributing factor in the genesis of cardiac thrombosis in Chagas' heart disease. As is the case for other heart diseases, blood stasis alone[22,27,28] or together with parietal endocarditis[29] is the mechanism thought to induce thrombosis in Chagas' heart disease.

Thromboembolic phenomena: The distribution of arterial beds affected by thromboembolic phenomena (Table IV) was similar to that described in a previous study on Chagas' heart disease[4] and to that detected in idiopathic congestive cardiomyopathy, although it differed from that reported for other types of heart disease[2,30] in the relative rarity of limb embolism. Since coronary embolism leading to myocardial infarction is relatively rare in all types of heart disease[31,32] it is interesting to note that 5 cases were detected in 1,345 cases studied.

The location of thrombus in the right atrial appendage in Chagasic hearts does not favor the detachment of emboli into the circulation, since there is little possibility for all the surfaces of a thrombus to be exposed to blood flow at this site.[33] This may be 1 of the reasons why systemic embolisms were more frequent in the material studied here.

It is not possible to determine with certainty the origin of an embolus in the pulmonary circulation detected in autopsy material, when cardiac thrombosis is present in the right chambers simultaneously with venous thrombosis. For this reason, those cases of Chagas' heart disease with both pulmonary embolism and venous thrombosis were excluded from the data presented in Table IV, but were reported in the footnote to the table. However, some investigators believe that the great majority of the pulmonary thromboembolic phenomena occurring in patients with Chagas' disease originate in the heart.[21,29] The systemic thromboembolic phenomena unrelated to cardiac thrombosis of the left chambers in our study were for the most part healed infarctions. A certain number of cases, however, consisted of recent processes, at times related to patient death. We do not believe that these thromboembolic phenomena without demonstrable cardiac origin should be considered to be cryptogenic,[33] since it is highly

possible that they arose from small cardiac thrombi released into the circulation.

Clinical implications: Obviously, deaths related to pulmonary thromboembolic phenomena are more prevalent than deaths related to systemic phenomena, since the latter are more frequent in the kidneys and spleen, where they are not lethal. A higher mortality rate occurs in patients with Chagas' heart disease with multiple thromboembolic phenomena. The recurrence of such episodes is potentially more dangerous.[34] For these persons, prophylaxis of the thromboembolic phenomena with anticoagulant therapy should be considered, especially since there is no contraindication for the treatment of patients with Chagas' heart disease. Prophylaxis by surgical therapy either by right atrial appendagectomy[35] or by apical aneurysmectomy[18] is not practical in view of the large number of patients with Chagas' heart disease. However, a few selected patients affected by arrhythmias whose disease could not be controlled by classic drug treatment have undergone left apical aneurysmectomy with good results,[36] both in terms of arrhythmia treatment and thromboembolism prophylaxis.

Aortic Valve Closure and Cardiac Vibrations in the Genesis of the Second Heart Sound

MARKKU KUPARI, MD

Simultaneous M-mode echocardiograms and external phonocardiograms were recorded in 15 healthy subjects to evaluate the genesis of the second heart sound. The onset of the second sound was found synchronous with the coaptation of the aortic valve cusps and a sharp vibration on the aortic wall. The closed valve was oscillating for 30 to 45 ms after the coaptation of the cusps. Magnified echocardiographic studies of the interventricular septum revealed a consistent, momentary quiver across the septal myocardium a mean of 4 ms after the onset of the second sound. In most subjects, a transient myocardial vibration was observed in temporal association with the first heart sound as well. The present observations suggest that the aortic valve closure initiates the production of the second heart sound, the main audible component resulting, however, from vibrations in the cardiac structures after the valve closure.

The exact genesis of the heart sounds is still a matter of contradictory opinions. Regarding the second sound, the major disagreement concerns the contribution of the aortic valve closure. According to the valvular theory,[1] the first component of the second sound results from the coaptation of the aortic valve cusps, and recent echocardiographic studies show that the onset of the sound coincides exactly with the aortic valve closure.[2,3] Other investigators maintain, however, that the aortic valve closes silently, and the second sound originates from aftervibrations in the cusps and in the walls and blood columns of the aorta and left ventricle.[4–6] The energy for these oscillations would come either from sudden deceleration of forward flow[4,5] or from abruptly arrested backflow of blood in the aorta.[6] The theory of silent aortic valve closure is vindicated by both animal[7–9] and human[10,11] studies which have demonstrated by various techniques that the coaptation of valve cusps precedes the onset of the second sound by a few milliseconds.

The aim of the present echophonocardiographic study was to ascertain the temporal relationship between the second heart sound and the aortic valve closure in normal subjects. Other possible echocardiographic correlates of the second sound were searched as well.

Methods

Subjects: The study group comprised 15 healthy men aged 23 to 30 years. They were selected from a large group of volunteers on the basis of a possibility of obtaining technically excellent left ventricular echocardiograms.

From the Cardiovascular Laboratory, Helsinki University Central Hospital, and the Research Laboratories of the State Alcohol Monopoly (Alko), Helsinki, Finland. Manuscript received February 24, 1983, accepted March 18, 1983.

Address for reprints: Markku Kupari, MD, Cardiovascular Laboratory, Helsinki University Central Hospital, SF-00290 Helsinki 29, Finland.

Echocardiography: The ultrasonic examinations were performed using an Irex System II echocardiograph equipped with a 2.25 MHz medium focused transducer and a fiber optic stripchart recorder. The repetition frequency of the transducer was 1,000 impulses/second. An M-mode echocardiogram of the left ventricle was first recorded with the transducer on the standard interspace[12] to the left of the sternum and the ultrasonic beam directed just below the mitral valve tips across the left ventricle. Appropriately magnified M-mode echoes were recorded thereafter separately from the interventricular septum and the posterior wall without changing the transducer location and with only minor alterations in the beam direction relative to the heart. Finally, the transducer was angulated towards the right shoulder and M-mode studies of the aortic root valves were performed.

Phonocardiography: The phonocardiograms were recorded externally from the second intercostal space at the left sternal border with the use of an Irex heart sound microphone over a frequency range of either 250 to 2,000 Hz (6 dB/octave roll at the lower end) or 350 to 2,000 Hz (12 dB/octave roll at the lower end), or both. The recordings were performed simultaneously with the echocardiograms and a lead II electrocardiogram as black on white, thermally processed tracings at a speed of either 100 or 200 mm/s. The intensity of the records tended to be unacceptably weak when the higher speed was used, so most of the analyses were made on records taken at the speed of 100 mm/s.

Measurement technique: The time intervals between the onset of the second sound and its echocardiographic correlates were measured using an x-y digitizer and a PDP 11/30 computer. The absolute intervals were averaged from 5 consecutive cardiac cycles and made to the nearest even 5 ms corresponding to a measurement accuracy of 0.5 mm.

Results

Aortic studies: Acceptable aortic studies, with sufficient simultaneous visualization of the right and noncoronary cusps (Fig. 1), were obtained in 8 of the 15 subjects. The coaptation of the valve cusps coincided with the onset of the first vibration of the second heart

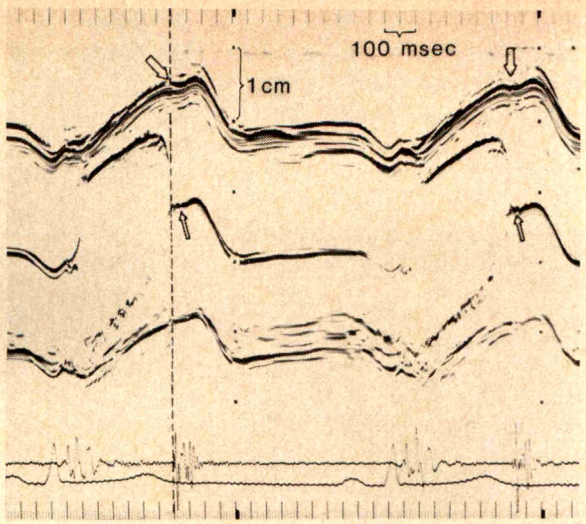

FIGURE 1. M-mode echocardiographic study of the aortic root demonstrating the simultaneity between the onset of the second heart sound and the aortic valve closure. Note also the coincident notch on the aortic wall and the aftervibrations in the closed valve (**arrows**). The chart speed was 100 mm/s.

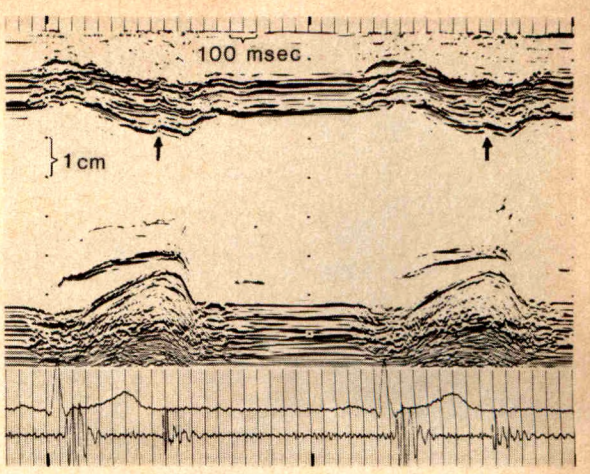

FIGURE 2. Standard M-mode echocardiogram of the left ventricle showing the sharp notch on the endocardial wave form of the interventricular septum (**arrows**). The chart speed was 100 mm/s.

sound; their time interval was 0 ms in each of these subjects. A sharp notch was invariably observed on the aortic wall occurring synchronously with the valve closure and the onset of the sound (Fig. 1). In most of these subjects, the closed aortic valve showed rapid vibrations lasting for approximately 30 to 45 ms after the point of collision of the cusps (Fig. 1).

Left ventricular studies: High-quality echocardiograms were obtained from the left ventricle and separately from the interventricular septum and posterior wall in each of the 15 subjects. The left ventricular studies demonstrated the presence of a septal notch in close temporal association with the second heart sound in each subject (Fig. 2). The magnified echocardiographic studies showed that, superimposed on the relatively smooth septal notch, there was a sharp, momentary quiver discernible not only on the endocardial echo but extending across the thickness of the septal myocardium (Fig. 3 and 4). The time interval from the onset of the second sound to the trough of the septal notch was 0 ms in 4 subjects and 5 ms in 11 subjects (mean 3.7 ms). In many of the latter subjects, the sharp peak of the notch coincided with the peak of the first high-amplitude vibration of the second sound. Magnified studies of the posterior wall showed in some subjects small inflections or discontinuities on the endocardial and myocardial echoes during the second sound. Yet, these were not distinct enough to allow their exact timing in relation to the phonocardiogram. Even though the genesis of the first heart sound was not specifically addressed in the present study, a relatively sharp septal quiver was noticed in most subjects in close temporal association with the first sound as well (Fig. 3B and 4).

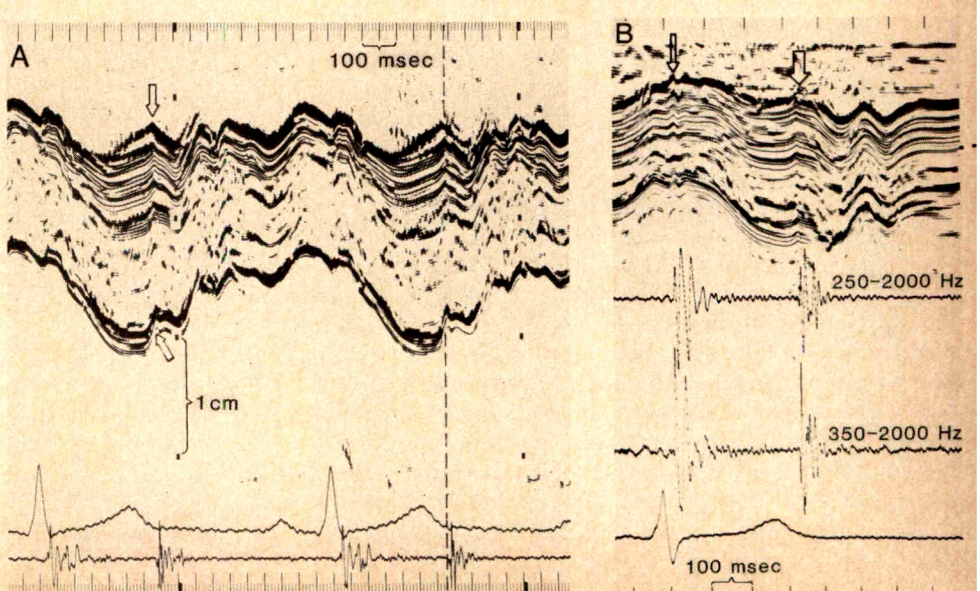

FIGURE 3. Magnified septal echocardiograms from 2 subjects (**A** and **B**) demonstrating the momentary myocardial quiver (**broad arrows**) immediately after the onset of the second heart sound. Note also the relatively sharp septal vibration during the first heart sound (**B, thin arrow**). The chart speed was 100 mm/s.

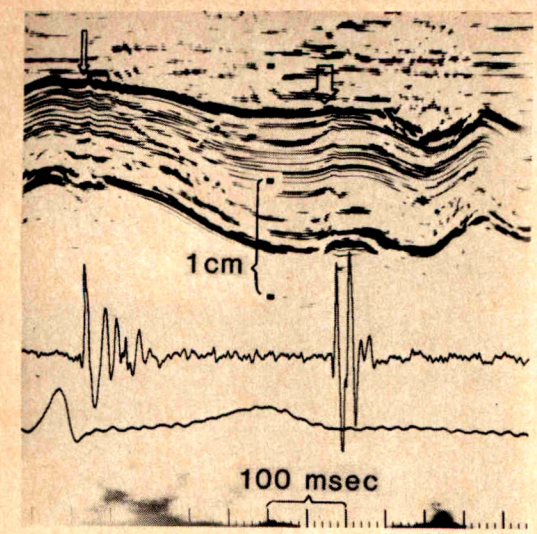

FIGURE 4. Magnified septal study at a chart speed of 200 mm/s from the same subject as in Figure 3B. The myocardial vibrations during the first and second sounds are clearly discernible (**arrows**).

Discussion

Methodologic considerations: In describing movements with time in the structures of the heart and great vessels, M-mode echocardiography provides in fact a kind of "phonocardiogram of reflected ultrasound." With a repetition frequency of 1,000 impulses/second, this technique should be able to detect correlates of the audible heart sounds even in their high-frequency range. This was verified in the present study when high-quality, magnified echocardiograms showed vibrations in the aortic valve and walls as well as in the ventricular myocardium in temporal association with the second heart sound. The most important limitation of the echophonocardiographic technique is that with a recording speed of 100 to 200 mm/s, the accuracy of measuring time intervals cannot be better than perhaps from 3 to 5 ms. This may be of significance since some investigators have claimed, on the basis of high-speed cineangiographic studies in dogs, that the onset of the second sound follows the aortic valve closure by an interval of only 0.5 ms.[5] It is self-evident that 2 events such a minute time interval apart would be interpreted as simultaneous by the present echophonocardiographic method.

Mechanism of the second heart sound: In spite of the aforementioned methodologic reservation, it proved rewarding to scrutinize the timing of the echocardiographic phenomena in relation to the phonocardiogram. The simultaneity between the onset of the second sound on the one hand and the coaptation of the aortic valve cusps and the coincident momentary vibration of the aortic wall on the other hand suggests that the valve closure indeed initiates the sound production. This observation agrees with some of the comparable earlier echocardiographic studies,[2,3] though not with all of them,[9–11] and supports the valvular theory about the genesis of the second sound.[1] Yet, the delay from the onset of the second sound to the momentary quiver of the septal myocardium, short as it was, suggests that the main audible component does not arise from the valve closure as such, but arises sooner from oscillations in the left ventricle immediately thereafter. Thus, the present findings agree also with those views maintaining that the second sound results mainly from vibrations in the "total cardiohemic system" after the aortic valve closure.[5,6,8]

The end-systolic septal notch: The septal notch described in the present study is not an entirely new finding. McDonald et al[13] reported in 1972 that the waveform of the echo from the left side of the septum has "a curious, notched appearance." They attributed this notch to a movement of the whole heart anteriorly during late systole and posteriorly during early diastole and postulated that a counterclockwise rotation of the heart was also contributory. Later, Assad-Morell et al[14] reported that the notch of the normal septal motion is associated in time with the end of the electrocardiographic T wave and with the carotid incisura. Also, they ascribed the notch to a twisting movement of the whole heart. Neither of these groups of authors recognized, however, the momentary quiver of the septal myocardium that is superimposed on the otherwise smooth-appearing notch and that relates to the genesis of the audible second heart sound, as likely as not. Interestingly, Sabbah and Stein[5] have found end-systolic notches on the left ventricular pressure tracing coincident with the components of the second sound. These pressure oscillations, which were observed both in humans and in dogs, to all appearance represent equivalents of the myocardial vibrations visualized echocardiographically for the first time in the present study.

Analysis of the Amount of Tricuspid Valve Anular Dilatation Required to Produce Functional Tricuspid Regurgitation

JOSE L. UBAGO, MD, ALVARO FIGUEROA, MD, ALBERTO OCHOTECO, MD, THIERRY COLMAN, MD, RAFAEL M. DURAN, MD, and CARLOS G. DURAN, MD, PhD

To determine the critical anular dilatation required for functional tricuspid regurgitation (TR) and the role of systolic anular shortening in the severity of TR, 67 patients in whom right ventriculography had been performed were studied. These patients were classified into group I, control (n = 12), and group II, patients with rheumatic valvular disease (n = 55). Group II patients were subclassified as follows: IIa, without TR (n = 19); IIb, with mild TR (n = 22); and IIc, with moderate to severe TR (n = 14). The angiographic maximal early systolic and minimal end-systolic diameters were measured. The shortening of the tricuspid anulus was expressed as percent reduction of the maximal diameter. The average maximal diameter (mm/m^2) was: group I, 21 ± 2; group IIa, 24 ± 2; group IIb, 31 ± 4; and group IIc, 37 ± 4. The average minimal diameter (mm/m^2) was: group I, 15 ± 2; group IIa, 18 ± 2; group IIb, 23 ± 2; and group IIc, 31 ± 3. The average percent shortening was: group I, 30 ± 7%; group IIa, 25 ± 7%; group IIb, 26 ± 5%; and group IIc, 15 ± 3%. The rheumatic patients had a larger maximal diameter than did those in the control group. Anular shortening was reduced only in the group with moderate to severe TR and preserved in the other groups, including those with mild TR. The critical diameter was determined to be between the maximal diameter in the rheumatic patients without TR and the minimal diameter in the patients with moderate to severe TR, or 27 mm/m^2. Thus this easily measured parameter can determine the presence and significance of functional TR, adding objectivity to the angiographic diagnosis of TR.

Better diagnostic methods[1–5] and surgical techniques for the treatment of tricuspid regurgitation (TR)[6–8] have increased the awareness of its frequency and its importance in the results of mitral valve surgery.[9,10] Although the postmortem and intraoperative direct observation of the tricuspid valve has shown a high percentage of organic lesions, functional TR remains common.[11,12] It is generally accepted that this is caused by anular dilatation secondary to right ventricular (RV) failure due to altered contractility, load, or both.[9,13] Tsakiris et al[14] experimentally and Tei et al[15] echocardiographically in human subjects have shown that the size of the normal tricuspid valve anulus does not remain constant during the cardiac cycle. Simon et al[16] recently reported that functional TR decreased or disappeared after mitral repair if the systolic shortening of the anulus improved. Our work was designed to determine (1) the critical point at which progressive anular dilatation produces TR, and (2) the role of systolic reduction of the anulus in the severity of TR.

Methods

Patients: To study the dynamics involved in the closure of the tricuspid valve, 67 patients were selected out of the 265 consecutive patients in whom RV angiography had been performed following our previously described method.[5] This selection was based on certain criteria: (1) good quality angiograms were required together with the absence of premature ventricular contractions at the time of contrast injection; (2) patients with congenital disease, primary pulmonary hypertension, cardiomyopathy, or myocardial infarction were excluded; and (3) among the patients with rheumatic valvular disease and angiographic TR, all had to have undergone surgery and have an operative report confirming the absence of organic tricuspid disease (that is, cusp thickening or commissural fusion).

The average age was 48 ± 11 years (range 16 to 70); 34 patients were male and 33 female. These 67 patients were divided into 2 groups:

Group I—Control group: This group included 12 patients with sinus rhythm. Seven patients had a normal heart. Among

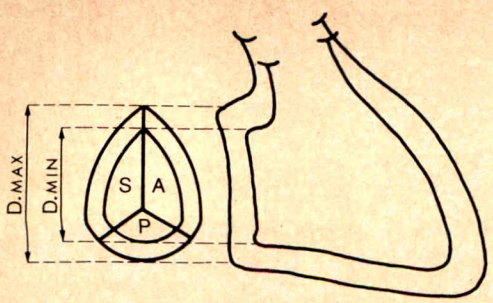

FIGURE 1. Diagrams of the right ventriculogram, frontal view of the tricuspid valve, and the measured maximal and minimal tricuspid diameters. A = anterior cusp, D. MAX = early systolic diameter; D. MIN = end-systolic diameter; P = posterior cusp; S = septal cusp.

the 7, 2 had functional murmurs, 3 had atypical angina, and 2 pulmonary disease. The other 5 patients had coronary disease without dyskinesia.

Group II—Rheumatic valvular disease: This group included 55 patients. According to the absence or presence and degree of TR they were classified into 3 further groups: *Group IIa:* Among these 19 patients without angiographic TR, 6 had mitral stenosis, 6 mitral disease, and 7 mitral and aortic disease. Fourteen patients had sinus rhythm and 5 atrial fibrillation. *Group IIb:* Among these 22 patients with mild TR, 7 had mitral stenosis, 9 mixed mitral disease, 5 mitral and aortic disease, and 1 aortic disease. All underwent surgery; after digital exploration the surgeon reported the absence of organic tricuspid disease. The functional TR was confirmed in only 9 patients. None of the 22 had the tricuspid valve repaired. Six patients had sinus rhythm and 16 atrial fibrillation. *Group IIc:* Among these 14 patients with a moderate to severe TR, 2 had mitral stenosis, 4 mixed mitral disease, and 8 mitral and aortic disease. All had the tricuspid valve repaired after confirmation of the absence of an organic lesion. All but 1 had atrial fibrillation.

Catheterization procedures: The patients were premedicated with diazepam (10 mg orally) 30 minutes before catheterization. A percutaneous femoral access was used in every patient for standard right- and left-sided cardiac catheterization. Pressures were measured at the mid-thoracic point with a Hewlett-Packard 1280 transducer and recorded with a Hewlett-Packard amplifier and recorder. Cardiac output was determined by the Fick method. All 67 patients underwent biventriculography. Fifteen minutes after left ventriculography, RV angiography was carried out following the method previously described by us.[5] Essentially it entails the use of a balloon catheter that becomes trapped in the trabeculae and, because of its ductility, does not induce false regurgitations. RV angiography was performed in the 30° right anterior oblique projection. Forty-five ml of 76% Urografin® (meglumine diatrizoate) was injected in 3 seconds with simultaneous recording of the electrocardiogram to detect the presence or absence of premature ventricular contractions. Filming was done through a Hiperlux Amplifier (CGR) in a Camaflex GV-35 mm camera at 50 frames/s. RV volumes were calculated with the Ferlinz method.[17] X-ray magnification was

II: Valvular heart disease						
IIa. Without TR (n = 19)	24 ± 2	18 ± 2	25 ± 7	87 ± 20	48 ± 13	44 ± 7
IIb. With mild TR (n = 22)	31 ± 4	23 ± 2	26 ± 5	95 ± 31	56 ± 28	44 ± 9
IIc. With moderate to severe TR (n = 14)	37 ± 4	31 ± 3	15 ± 3	110 ± 26	71 ± 23	36 ± 9

Values are expressed as means ± standard deviation.
D max = maximal early systolic diameter; D min = minimal end-systolic diameter; EDV = end-diastolic volume; EF = ejection fraction; ESV = end-systolic volume; STA = shortening tricuspid anulus; TR = tricuspid regurgitation.

corrected by relating the catheter diameter to its radiographic diameter.

Analysis of RV angiograms: The degree of TR was graded as follows: *mild:* partial, nonhomogeneous opacification of the right atrium, including constant early or early mid-systolic regurgitations; *moderate:* almost complete and homogeneous filling of the right atrium; and *severe:* immediate filling of the whole right atrium and both caval veins.

In each RV angiogram the maximum diameter of the anular region of the tricuspid valve in early systole (D max) and the minimal diameter in late systole (D min) were measured (Fig. 1). These measurements were corrected in relation to the linear amplificaton of the angiographic image (CF). These values were related to the patient's body surface (BSA), so that diameter index (mm/m^2) = [D (mm) × CF]/BSA (m^2).

The systolic shortening of the tricuspid anulus (STA) was expressed as the percentage of decrease in diameter, related to the maximal diameter (D max): STA (%) = [(D max − D min)/D max] × 100.

To reduce the influence of the variable diastolic times in the patients with atrial fibrillation, these systolic measurements were performed only when the previous diastolic time was of 0.32 to 0.6 second.

To determine the critical anular dilatation beyond which TR always follows, it was assumed that it should be larger than the maximal diameter found in the patients without TR and smaller than the minimal diameter found in the patients with moderate to severe (pansystolic) TR.

Statistical analysis: The data were analyzed by standard statistical methods including one-way analysis of variance and the unpaired Student's *t* test. Tukey's method was used to compare multiple means if analysis of variance confirmed that at least 1 pair of means was significantly different.

Results

The more relevant hemodynamic data for each group of patients are presented in Table I. Table II summarizes the angiographic data for each group of patients.

The average maximal diameter of the control group (normal tricuspid function) was 21 ± 2 mm/m^2. This diameter was larger although without statistical significance in the patients with rheumatic valve disease without TR (group IIa). This increase in maximal diameter was much more evident among patients with TR (groups IIb and IIc) ($p < 0.01$). There was also a statistical difference between these last 2 groups ($p < 0.01$).

The average minimal diameter of the control group was 15 ± 2 mm/m^2. This diameter was larger in group IIa and even more so in group IIb. The largest diameter was found in the group with moderate to severe TR (group IIc). These differences among groups were statistically significant ($p < 0.01$). The average systolic shortening of the tricuspid anulus in the control group was 30 ± 7%. Although the average shortening in groups IIa and IIb was smaller, this finding had no statistical significance. The percent shortening in group IIc (moderate to severe TR) was 15 ± 3%, significantly lower than in all the other groups ($p < 0.01$).

Comparison of the end-diastolic and end-systolic volumes in the 4 groups showed significant differences ($p < 0.01$) only in the control group and the patients with moderate to severe TR (group IIc). The ejection fraction varied significantly between the control group and each group with rheumatic disease.

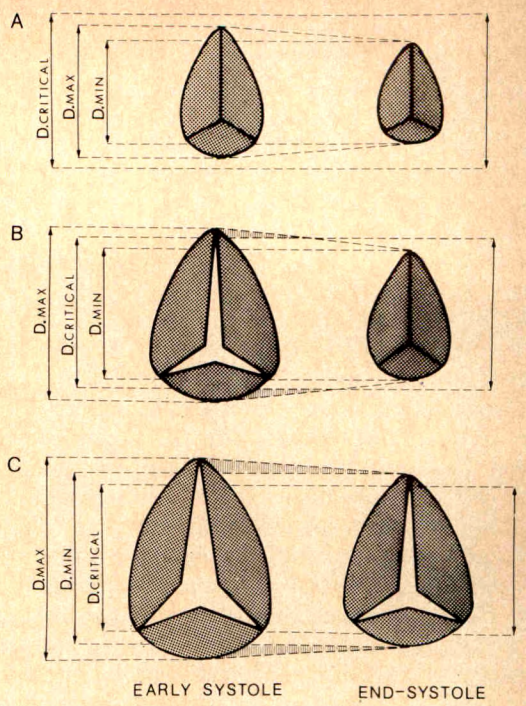

FIGURE 2. Diagram of the tricuspid valve in patients with rheumatic heart disease. **Panel A,** patients without TR (group IIa). Both maximal early systolic diameter (D. MAX) and minimal end-systolic diameter (D. MIN) are below the critical diameter. Cusp apposition is present throughout systole. **Panel B,** patients with mild TR (group IIb). D. MAX is larger and D. MIN is smaller than the critical diameter (D. CRITICAL). No cusp apposition during early and mid-systole occurs. **Panel C,** patients with moderate to severe TR (group IIc). D. MAX and D. MIN are above the critical diameter. No cusp apposition occurs. The **shaded areas** represent the systolic period during which TR is present.

The critical diameter above which regurgitation appears must be larger than the maximal diameter in those patients without TR, that is, the control and IIa groups. As the maximal diameter in group IIa is larger than that in the control group, the critical diameter must be higher than 24 ± 2 mm/m^2. This value is similar to the minimal diameter found in the patients with mild TR (group IIb, 23 ± 2 mm/m^2). This critical diameter must also be smaller than the minimal diameter found in patients with moderate to severe TR (31 ± 3 mm/m^2). Again, this value is similar to the maximal diameter in those with mild TR (group IIb, 31 ± 4 mm/m^2). Therefore, the critical diameter must be between 24 ± 2 and 31 ± 3. A working figure of 27 mm/m^2 is suggested. Figure 2 presents a schematic summary of our findings.

Discussion

Our angiographic measurements of the tricuspid anulus were very similar to those found by others.[1] However, we thought it would be more precise to relate them to the patient's body surface area (mm/m^2). These measurements represent only one of the tricuspid diameters and its variations during cardiac cycle in normal patients and patients with TR. The object of this work was not to determine the measurement of the tricuspid anulus circumference. However, if our measured max-

imal diameter is used to calculate the diastolic anulus circumference, this value corresponds with the previously reported postmortem studies[13,18,19] and with the echocardiographically calculated maximal circumference.[15] This is only so if it is assumed that in diastole the tricuspid orifice becomes circular. Conversely, the minimal circumference obtained from our minimal diameter cannot be similar to the reported echocardiographic values[15] because of the noncircular structure of the tricuspid orifice.

The anular dilatation in functional TR has been regularly reported in surgical and postmortem studies and accepted as the cause of regurgitation.[9,13] Tsakiris et al[14] showed in the dog and Tei et al[15] showed in man the role of anulus reduction in the normal tricuspid closure. The latter group also showed the anular dilatation and decreased area reduction in patients with TR. In an angiographic study, Simon et al[16] showed a relationship between postoperative improvement in the tricuspid anulus shortening and the reduction in functional TR. Furthermore, there must be a critical diameter above which TR follows due to the nonperfect coaptation of the leaflets. This critical closure diameter must be close to the largest maximal diameter found in patients without regurgitation. It must also be smaller than the minimal systolic diameter in patients with pansystolic regurgitation. This figure must therefore be between 24 ± 2 and 31 ± 3 mm/m^2: that is, between 26 and 28 mm/m^2. It can therefore be assumed that the critical diameter is approximately 27 mm/m^2. Given a ventricular pressure, TR is related to the incompetent orifice. This regurgitation starts at the maximal diameter and is progressively reduced until disappearing when the orifice reaches the critical diameter—that is, 27 mm/m^2. The larger the initial maximal diameter, the larger percent shortening required to achieve competence.

Our patients with a normal tricuspid valve and without altered contractility and load (control group) have smaller maximal and minimal diameters and larger percentages of shortening than any other group. The patients with rheumatic valvular disease but no TR (group IIa) had a slight dilatation of the tricuspid anulus or maximal diameter with a preserved shortening. As this maximal diameter is still below the critical diameter, no regurgitation ensues. The patients with mild and in many cases nonpansystolic TR (group IIb) had an anular shortening close to normal but with a large diastolic anular dilatation. Because of a satisfactory shortening, their minimal systolic diameter remained slightly larger than the maximal diameter in the normal patients but smaller than the maximal diameter in the rheumatic patients without TR (23 ± 2 versus 21 ± 2 and 24 ± 2 mm/m^2). All the latter figures are below the critical diameter. In this group the maximal diameter is above the critical diameter while the minimal diameter is below the critical diameter. The regurgitation cannot be pansystolic because sometimes during systole the shortening achieves a diameter below the critical figure.

The maximal diameter in the patients with moderate to severe TR (group IIc) was the largest of all groups and with a severe impairment in the percentage of shortening. The end-systolic or minimal diameter remained above the critical diameter, and therefore the regurgitation is present throughout systole.

The concept of critical anular dilatation simplifies the angiographic diagnosis of functional TR. If a measured systolic anulus diameter is above the critical value, then TR exists. If the late systolic diameter is above the critical value, this TR is moderate to severe. Second, the severity of the regurgitation will also be given both by the maximal diameter and the percentage of shortening of the anular region. When the maximal diameter is above the critical diameter TR exists, but its severity will depend on the capacity to shorten it below the critical value before the end of systole.

This method has the practical value of making more reliable the diagnosis of the presence and severity of functional TR. It eliminates the frequent pitfalls of previous angiographic methods such as quantification of right atrial opacification in the presence of variable right atrial sizes, premature ventricular beats, and altered right ventricular contractility. In these situations measurement of the anulus is always possible and therefore independent of these factors.

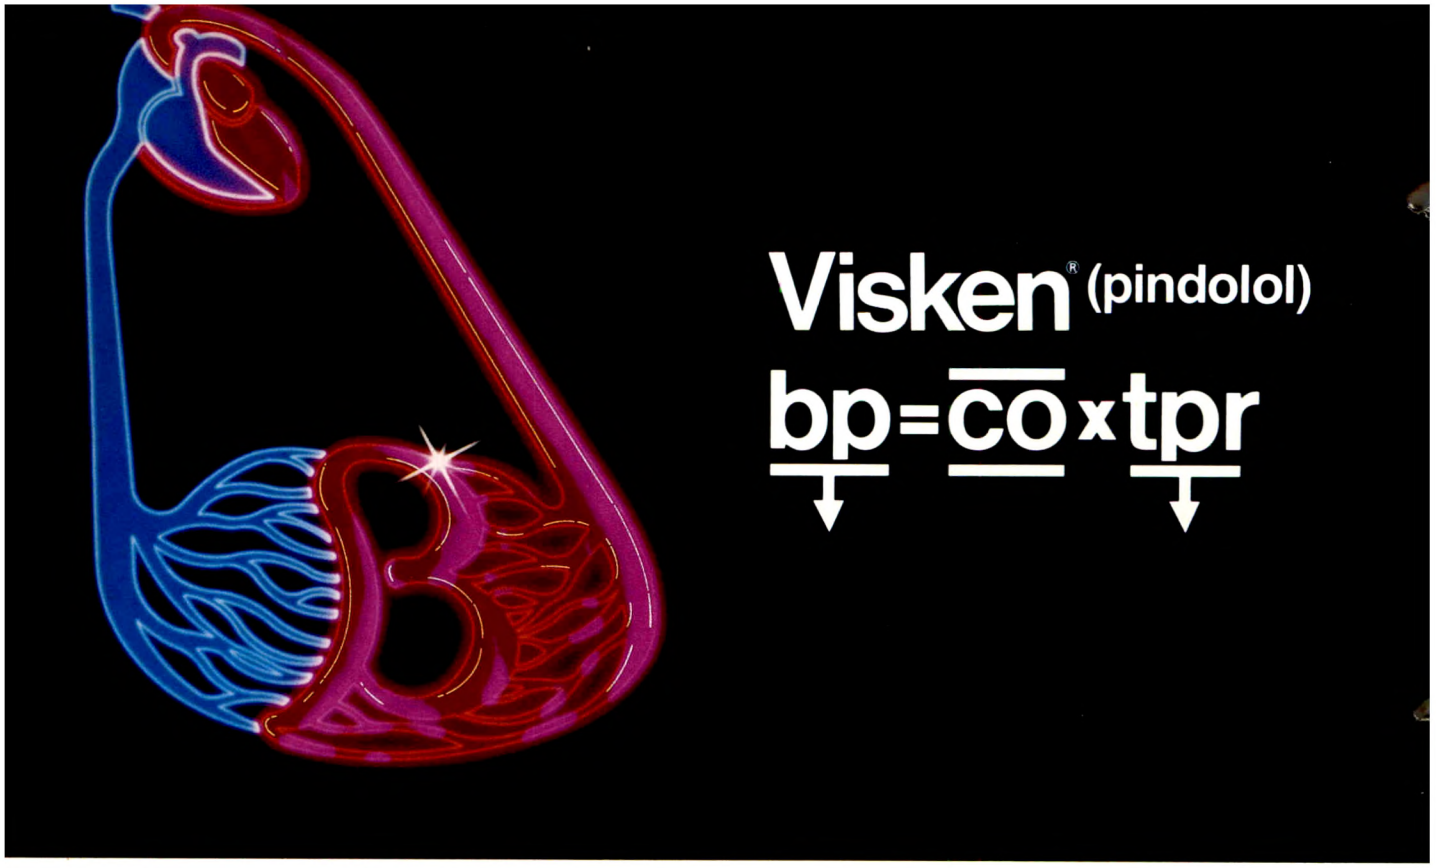
The Visken® (pindolol) difference
All other beta blockers
bp = co x tpr
Visken (pindolol)
bp = co x tpr



Makes hemodynamic sense in the treatment of hypertension

Reduces blood pressure

It's as effective as propranolol in normalizing blood pressure (dbp ≤ 90 mmHg) when used alone. It's also effective when used in combination with a diuretic.[1]

Has little effect on resting cardiac output

Unlike other beta blockers, Visken (pindolol) maintains resting cardiac output during long-term therapy. The clinical significance of this has not been evaluated.

Reduces total peripheral resistance*

Visken (pindolol) reduces one of the recognized components of hypertension: increased peripheral resistance.* Studies of 178 patients treated with Visken (pindolol) for at least two weeks have shown that Visken therapy reduces total peripheral resistance.[1]

Reduces exercise-induced tachycardia

Like other beta blockers, Visken (pindolol) blocks stimulation by catecholamines to reduce exercise-induced increases in systolic blood pressure and heart rate.

© 1983 Sandoz, Inc.

*The clinical significance has not been evaluated. See clinical significance statement on facing page of this advertisement.

Has little effect on resting heart rate

Visken® (pindolol) produces minimal changes in resting heart rate. Average reduction: 4-8 beats/minute.

The clinical significance has not been evaluated

The clinical significance of maintaining resting cardiac output, resting heart rate and reduced total peripheral resistance has not been evaluated and there is no evidence or reason to believe that exercise cardiac output is less affected by Visken (pindolol) than other beta blockers.

Maintains renal blood flow

Visken (pindolol) reduces supine and standing blood pressure while maintaining effective renal plasma flow and glomerular filtration rates.[2]

Favorable side effect profile

Low incidence of bradycardia

Low incidence of cold extremities

Visken (pindolol) is contraindicated in:

1) bronchial asthma
2) overt cardiac failure
3) cardiogenic shock
4) second- and third-degree heart block
5) severe bradycardia

*See clinical significance statement.

Please see next page of this advertisement for brief summary of prescribing information.

Visken® (pindolol)

Available in 5 mg and 10 mg tablets

Convenient bid dosage

Dosage should be titrated on an individual basis.
Many patients respond to 10-30 mg a day in divided doses.

Before prescribing or administering, see package circular for full product information. The following is a brief summary.

INDICATIONS AND USAGE

Visken (pindolol) is indicated in the management of hypertension. It may be used alone or concomitantly with other antihypertensive agents, particularly with a thiazide type diuretic.

CONTRAINDICATIONS

Visken (pindolol) is contraindicated in: 1) bronchial asthma; 2) overt cardiac failure; 3) cardiogenic shock; 4) second and third degree heart block; 5) severe bradycardia; (see Warnings).

WARNINGS

Cardiac Failure: Sympathetic stimulation may be a vital component supporting circulatory function in patients with congestive heart failure, and its inhibition by beta-blockade may precipitate more severe failure. Although beta-blockers should be avoided in overt congestive heart failure, if necessary, Visken (pindolol) can be used with caution in patients with a history of failure who are well-compensated, usually with digitalis and diuretics. Beta-adrenergic blocking agents do not abolish the inotropic action of digitalis on heart muscle.

In Patients Without A History of Cardiac Failure: In patients with latent cardiac insufficiency, continued depression of the myocardium with beta-blocking agents over a period of time can in some cases lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Visken (pindolol) therapy should be withdrawn (gradually if possible).

Exacerbation of Ischemic Heart Disease Following Abrupt Withdrawal: Hypersensitivity to catecholamines has been observed in patients withdrawn from beta-blocker therapy; exacerbation of angina and, in some cases, myocardial infarction have occurred after *abrupt* discontinuation of such therapy. When discontinuing chronically administered Visken (pindolol), particularly in patients with ischemic heart disease, the dosage should be gradually reduced over a period of one to two weeks and the patient should be carefully monitored. If angina markedly worsens or acute coronary insufficiency develops, Visken (pindolol) administration should be reinstituted promptly, at least temporarily, and other measures appropriate for the management of unstable angina should be taken. Patients should be warned against interruption or discontinuation of therapy without the physician's advice. Because coronary artery disease is common and may be unrecognized, it may be prudent not to discontinue Visken (pindolol) therapy abruptly even in patients treated only for hypertension.

Nonallergic Bronchospasm (e.g., chronic bronchitis, emphysema)—Patients with Bronchospastic Diseases Should in General Not Receive Beta-Blockers: Visken (pindolol) should be administered with caution since it may block bronchodilation produced by endogenous or exogenous catecholamine stimulation of $beta_2$ receptors.

Major Surgery: Because beta blockade impairs the ability of the heart to respond to reflex stimuli and may increase the risks of general anesthesia and surgical procedures, resulting in protracted hypotension or low cardiac output, it has generally been suggested that such therapy should be withdrawn several days prior to surgery. Recognition of the increased sensitivity to catecholamines of patients recently withdrawn from beta-blocker therapy, however, has made this recommendation controversial. If possible, beta-blockers should be withdrawn well before surgery takes place. In the event of emergency surgery, the anesthesiologist should be informed that the patient is on beta-blocker therapy. The effects of Visken® (pindolol) can be reversed by administration of beta-receptor agonists such as isoproterenol, dopamine, dobutamine, or levarterenol. Difficulty in restarting and maintaining the heart beat has also been reported with beta-adrenergic receptor blocking agents.

Diabetes and Hypoglycemia: Beta-adrenergic blockade may prevent the appearance of premonitory signs and symptoms (e.g., tachycardia and blood pressure changes) of acute hypoglycemia. This is especially important with labile diabetics. Beta-blockade also reduces the release of insulin in response to hyperglycemia; therefore, it may be necessary to adjust the dose of antidiabetic drugs.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta-blockade which might precipitate a thyroid crisis.

PRECAUTIONS

Impaired Renal or Hepatic Function: Beta-blocking agents should be used with caution in patients with impaired hepatic or renal function. Poor renal function has only minor effects on Visken (pindolol) clearance, but poor hepatic function may cause blood levels of Visken (pindolol) to increase substantially.

Information for Patients: Patients, especially those with evidence of coronary artery insufficiency, should be warned against interruption or discontinuation of Visken (pindolol) therapy without the physician's advice. Although cardiac failure rarely occurs in properly selected patients, patients being treated with beta-adrenergic blocking agents should be advised to consult the physician at the first sign or symptom of impending failure.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients receiving Visken (pindolol) plus a catecholamine depleting agent should, therefore, be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Visken (pindolol) has been used with a variety of antihypertensive agents, including hydrochlorothiazide, hydralazine, and guanethidine without unexpected adverse interactions.

Carcinogenesis, Mutagenesis, Impairment of Fertility: In chronic oral toxicologic studies (one to two years) in mice, rats, and dogs, Visken (pindolol) did not produce any significant toxic effects. In two-year oral carcinogenicity studies in rats and mice in doses as high as 59 mg/kg/day and 124 mg/kg/day (50 and 100 times the maximum recommended human dose), respectively, Visken (pindolol) did not produce any neoplastic, preneoplastic, or nonneoplastic pathologic lesions. In fertility and general reproductive performance studies in rats, Visken (pindolol) caused no adverse effects at a dose of 10 mg/kg.

In the male fertility and general reproductive performance test in rats, definite toxicity characterized by mortality and decreased weight gain was observed in the group given 100 mg/kg/day. At 30 mg/kg/day, decreased mating was associated with testicular atrophy and/or decreased spermatogenesis. This response is not clearly drug related, however, as there was no dose response relationship within this experiment and no similar effect on testes of rats administered Visken (pindolol) as a dietary admixture for 104 weeks. There appeared to be an increase in prenatal mortality in males given 100 mg/kg but development of offspring was not impaired.

In females administered Visken (pindolol) prior to mating through day 21 of lactation, mating behavior was decreased at 100 mg/kg and 30 mg/kg. At these dosages there also was increased mortality of offspring. Prenatal mortality was increased at 10 mg/kg but there was not a clear dose response relationship in this experiment. There was an increased resorption rate at 100 mg/kg observed in females necropsied on the 15th day of gestation.

Pregnancy—Category B: Studies in rats and rabbits exceeding 100 times the maximum recommended human doses, revealed no embryotoxicity or teratogenicity. Since there are no adequate and well-controlled studies in pregnant women, and since animal reproduction studies are not always predictive of human response, Visken (pindolol), as with any drug, should be employed during pregnancy only if the potential benefit justifies the potential risk to the fetus.

Nursing Mothers: Since Visken (pindolol) is secreted in human milk, nursing should not be undertaken by mothers receiving the drug.

Pediatric Use: Safety and effectiveness in children have not been established.

CLINICAL LABORATORY

Minor persistent elevations in serum transaminases (SGOT, SGPT) have been noted in 7% of patients during Visken (pindolol) administration, but progressive elevations were not observed and liver injury has not been reported in the medical literature over a ten (10) year period of marketing. Alkaline phosphatase, lactic acid dehydrogenase (LDH) and uric acid are also elevated on rare occasions. The significance of these findings is unknown.

ADVERSE REACTIONS

Most adverse reactions have been mild. The incidences listed in the following table are derived from 12 week comparative double-blind, parallel design trials in hypertensive patients given Visken (pindolol) as monotherapy, given various active control drugs as monotherapy, or given placebo. Data for Visken (pindolol) and the positive controls were pooled from several trials because no striking differences were seen in the individual studies, with one exception. The frequency of edema was noticeably higher in positive control trials (16% Visken (pindolol) vs 9% positive control) than in placebo controlled trials (6% Visken (pindolol) vs 3% placebo). The table includes adverse reactions reported in greater than 2% of Visken (pindolol) patients and other selected important reactions.

Body System/ Adverse Reaction	Total (Volunteered and Elicited) Visken (pindolol) (N = 322) %	Active Controls* (N = 188) %	Placebo (N = 78) %
Central Nervous System			
Anxiety	4	<1	1
Bizarre or Many Dreams	8	3	8
Dizziness	17	23	8
Fatigue	15	19	12
Hallucinations	1	0	0
Insomnia	19	8	12
Lethargy	3	6	4
Nervousness	11	5	9
Weakness	7	5	4
Autonomic Nervous System			
Paresthesia	5	2	8
Visual Disturbances	4	3	4
Cardiovascular			
Dyspnea	9	8	9
Edema	11	9	3
Heart Failure	2	<1	0
Palpitations	2	2	0
Weight Gain	3	5	0
Musculo-Skeletal			
Chest Pain	5	3	5
Joint Pain	11	6	8
Muscle Cramps	8	2	0
Muscle Pain	12	12	9
Gastrointestinal			
Abdominal Discomfort	7	7	5
Nausea	7	4	1
Skin			
Pruritus	2	<1	0
Rash	2	3	3

*Active Controls: Patients received either propranolol, α-methyldopa or a diuretic (hydrochlorothiazide or chlorthalidone).

The following selected (potentially important) adverse reactions were seen in 2% or fewer patients and their relationship to Visken (pindolol) is uncertain. AUTONOMIC NERVOUS SYSTEM: hyperhidrosis; CARDIOVASCULAR: bradycardia, claudication, cold extremities, heart block, hypotension, syncope, tachycardia; GASTROINTESTINAL: diarrhea, vomiting; RESPIRATORY: wheezing; UROGENITAL: impotence, pollakiuria; MISCELLANEOUS: eye discomfort or burning eyes.

POTENTIAL ADVERSE EFFECTS

In addition, other adverse effects not listed above have been reported with other beta-adrenergic blocking agents and should be considered potential adverse effects of Visken (pindolol).

Central Nervous System: Reversible mental depression progressing to catatonia; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block. See CONTRAINDICATIONS.

Allergic: Erythematous rash; fever combined with aching and sore throat; laryngospasm; respiratory distress.

Hematologic: Agranulocytosis; thrombocytopenic and non-thrombocytopenic purpura.

Gastrointestinal: Mesenteric arterial thrombosis; ischemic colitis.

Miscellaneous: Reversible alopecia; Peyronie's disease.

The oculomucocutaneous syndrome associated with the beta-blocker practolol has not been reported with Visken (pindolol) during investigational use and extensive foreign experience amounting to over 4 million patient-years.

OVERDOSAGE

No specific information on emergency treatment of overdosage is available. Therefore, on the basis of the pharmacologic actions of Visken (pindolol), the following general measures should be employed as appropriate in addition to gastric lavage:

Excessive Bradycardia: administer atropine; if there is no response to vagal blockade, administer isoproterenol cautiously.

Cardiac Failure: digitalize the patient and/or administer diuretic. It has been reported that glucagon may be useful in this situation.

Hypotension: administer vasopressors, e.g., epinephrine or levarterenol, with serial monitoring of blood pressure. (There is evidence that epinephrine may be the drug of choice.)

Bronchospasm: administer a $beta_2$ stimulating agent such as isoproterenol and/or a theophylline derivative.

A case of an acute overdosage has been reported with an intake of 500 mg of Visken (pindolol) by a hypertensive patient. Blood pressure increased and heart rate was ≥80 beat/min. Recovery was uneventful. In another case 250 mg of Visken (pindolol) was taken with 150 mg diazepam and 50 mg nitrazepam, producing coma and hypotension. The patient recovered in 24 hours.

DOSAGE AND ADMINISTRATION

The dosage of Visken (pindolol) should be individualized. The recommended initial dose of Visken (pindolol) is 10 mg b.i.d. alone or in combination with other antihypertensive agents. Many patients will respond to 15 mg per day (5 mg t.i.d.). The antihypertensive response usually occurs within the first week of treatment. If a satisfactory reduction in blood pressure does not occur within 2-3 weeks, the dose may be adjusted in increments of 10 mg per day at 2-3 week intervals up to a maximum of 60 mg per day.

HOW SUPPLIED

White, round, scored tablets: 5 mg and 10 mg, packages of 100. 5 mg tablets embossed "VISKEN 5" on one side, and "78-111" and scored on other side (NDC 0078-0111-05). 10 mg tablets embossed "VISKEN 10" on one side, and "78-73" and scored on other side (NDC 0078-0073-05). [VIS-Z2 9/1/82]

VIS-383-1

Effect of Pericardiocentesis on Right and Left Ventricular Function and Volumes in Pericardial Effusion

DANTE E. MANYARI, MD, WILLIAM J. KOSTUK, MD, and PAUL PURVES, RTNM

To assess the effects of pericardial effusion on ventricular performance and volumes, electrocardiographically gated blood pool cardiac scintigraphy was performed immediately before and after 14 pericardiocenteses in 10 patients, 7 men and 3 women, aged 28 to 73 years (mean 50). Cardiac tamponade was present in 5 patients. After removal of 140 to 1,100 ml of pericardial fluid (527 ± 305 ml [mean ± standard deviation]), left ventricular (LV) ejection fraction increased from 63 ± 5 to 64 ± 4% ($p > 0.05$) and right ventricular (RV) ejection fraction decreased from 47 ± 4 to 46 ± 2% ($p > 0.05$). LV end-diastolic and end-systolic volumes increased ($p < 0.01$) by 28 and 33%, and RV volumes by 40 and 43%, respectively. There were 8 patients with normal LV function (ejection fraction >60%) and 6 patients with subnormal LV function. Changes in ejection fraction were nonsignificant in the 4 subgroups. LV end-diastolic volume changes were more marked ($p < 0.01$) in patients with cardiac tamponade (+56%) than in those without tamponade (+17%), and in those with normal LV function (+36%) than in those with subnormal LV function (+21%). RV end-diastolic volume increased more markedly ($p < 0.05$) in patients with tamponade (+72%) than in those without tamponade (+23%), but were similar in patients with normal (+38%) and abnormal (+43%) LV function. After pericardiocentesis, RV volume increased more markedly than did LV volume. Thus, hemodynamic and clinical improvement after pericardiocentesis may be related only to an increase in stroke volume. RV and LV ejection fraction, a measure of myocardial contractility, was not affected significantly by the presence of pericardial effusion, even in those patients who had cardiac tamponade.

Although left ventricular (LV) function and volume changes produced by pericardial effusion have been assessed in many studies using experimental animal models,[1–5] studies in man have been limited.[6–9] No information is available regarding the effects of pericardial effusion on right ventricular (RV) function. Moreover, the results reported thus far have yielded conflicting results. LV ejection fraction (EF) was decreased,[1–4] increased,[5] or unchanged.[8] End-systolic dimension was relatively increased,[1,3] decreased,[5,8] or unchanged.[2,7] This study assesses RV and LV function and volumes before and after removal of pericardial fluid by means of the electrocardiographically (ECG)-gated blood pool cardiac scintigraphy.

From the Cardiac Investigation Unit, University Hospital, London, Canada, and the Cardiology Division, Department of Medicine, University of Calgary and The Foothills Hospital, Calgary, Canada. This study was supported in part by the Ontario Heart Foundation, Toronto, Canada. Manuscript received January 27, 1983; revised manuscript received April 6, 1983, accepted April 8, 1983.

Address for reprints: Dante E. Manyari, MD, Division of Cardiology, University of Calgary and the Foothills Hospital, 1403 29th Street, NW, Calgary, Alberta, Canada, T2N 2T9.

Methods

Patient population and study design: Consecutive patients undergoing therapeutic or diagnostic pericardiocentesis were included in this investigation if they had normal sinus rhythm and their clinical condition was stable. All studies included the following successive procedures: (1) duplicate acquisition of ECG-gated blood pool cardiac scintigraphy in the supine position after a 30-minute rest period; (2) pericardiocentesis and removal of as much pericardial fluid as possible; and (3) duplicate ECG-gated blood pool cardiac imaging acquisitions using the same patient and patient-camera positions as those used during the initial studies. Needle aspiration of pericardial fluid was performed using the subxiphoid approach under blood pressure and electrocardiographic monitoring. Patients did not receive intravenous fluids or medications during the study. Except for digitalis, all cardiac and vasoactive drugs were withheld for at least 24 hours before the investigations.

Radionuclide studies: Radionuclide studies were performed using standard equipment and techniques.[10] Briefly, each study consisted of 2-minute acquisition in the modified left anterior oblique projection. Analysis included the construction of variable ventricular regions of interest by an automated edge-detection algorithm for the left ventricle and a manual method for the right ventricle. Standard formulas were then used to calculate EF. The effects of pericardial fluid

TABLE I Clinical Data in 10 Patients With Pericardial Effusion During 14 Pericardiocenteses

Exp = expiratory; Insp = inspiratory; JVP = jugular venous pressure (in cm) above the angle of Louis; Per = pericardiocentesis; SBP = systolic blood pressure.

drainage on relative ventricular volumes were quantitated using the formula: %VV change = $100 \times [(VC\ AP/e^{-\lambda t}) - (VC\ BP)]/VC\ BP$, where VV = end-diastolic or end-systolic RV or LV volume, VC = normalized (that is, corrected for the actual frame duration and the number of cardiac cycles processed) RV or LV end-diastolic or end-systolic counts after pericardiocentesis (AP) and before pericardiocentesis (BP), and $e^{-\lambda t}$ = general equation for isotope decay. A positive value indicates a larger volume after pericardiocentesis. There was a good correlation between the 2 values obtained at each stage for RV and LV end-diastolic and end-systolic counts before ($r = 0.89$) and after ($r = 0.94$) pericardiocentesis. The effect of pericardiocentesis on relative LV stroke volume was assessed by the formula: %SV change = $100 \times [(SC\ AP/e^{-\lambda t}) - (SC\ BP)]/SC\ BP$, where SV = LV stroke volume, SC = normalized LV stroke counts, AP = after pericardiocentesis, BP = before pericardiocentesis, and $e^{-\lambda t}$ = general equation for isotope decay. A positive value indicates a larger SV after pericardiocentesis.

Statistical analysis and definitions: Pre- and postpericardiocentesis data were compared using Student's *t* test for paired measurements. To determine the significance of the different response to pericardiocentesis among various subgroups, 2-way analysis of variance followed by the Tukey test was used. Cardiac tamponade was defined by the presence of increased jugular venous pressure, a paradoxical arterial pulse, evidence of pericardial effusion, and the disappearance or diminution of these clinical signs after the removal of pericardial fluid. Paradoxical pulse was defined as an inspiratory decrease in systolic blood pressure >10 mm Hg.

Results

Fourteen studies were performed in 10 patients, 7 men and 3 women, aged 28 to 73 years (mean 50) (Table I). Pericardiocentesis was carried out for therapeutic reasons in 13 instances and for diagnostic purposes in 1 (Patient 10). Patients in the former group complained of dyspnea and easy fatigability and exhibited elevated venous pressure or paradoxical pulse. Symptoms and signs improved or resolved after pericardial drainage. No complications occurred during this investigation.

Cardiac tamponade was present in 5 patients. There were 8 patients with normal and 6 patients with subnormal LV function as indicated by LVEF <60%[11] or segmental wall motion abnormality or both in either or both pre- and postpericardiocentesis studies. The amount of pericardial fluid removed varied between 140 and 1,100 ml (527 ± 305 mean ± standard deviation). After pericardiocentesis the mean heart rate decreased by 6 ± 5 beats/min and the average systolic blood pressure increased by 15 ± 10 mm Hg. These changes were more marked in patients with cardiac tamponade and in those with subnormal LV function (Table II).

Ventricular function and volume changes: Neither RVEF nor LVEF changed significantly after pericardiocentesis in the entire population as a whole or in any of the subgroups (Table II). Before pericardiocentesis, mean RVEF was higher in patients without cardiac tamponade and in those with normal LV function. However, average RVEF after pericardiocentesis was not significantly different in any of the subgroups.

Ventricular volumes, contrary to EF, increased significantly after pericardiocentesis (Table II). Both RV and LV end-diastolic and end-systolic volumes increased in all subgroups, but these changes were greater in patients with cardiac tamponade. The increase in LV end-diastolic and end-systolic volume was quantitatively more marked in patients with cardiac tamponade than in those without tamponade, and in patients with normal LV function than in those with abnormal LV function. The increase in end-diastolic volume after

p values are noted for data before pericardiocentesis versus those after pericardiocentesis.
After = after pericardiocentesis; before = before pericardiocentesis; BP = blood pressure; EDV = end-diastolic volume; ESV = end-systolic volume; EF = ejection fraction; LV = left ventricular; NS = not significant; RV = right ventricular; SV = stroke volume.

pericardiocentesis was relatively larger in the right than in the left ventricle. LV stroke volume increased significantly after removing pericardiac fluid (Table II), and although patients with cardiac tamponade showed the more marked changes, an increase in LV stroke volume was seen in all patients during this investigation.

Discussion

The results of this study showed that the removal of pericardial fluid did not significantly change RVEF or LVEF even in patients with cardiac tamponade, whereas both RV and LV end-diastolic and end-systolic volume increased. Comparatively, larger volume changes were observed in the right than in the left ventricle. Patients with cardiac tamponade displayed the largest volume changes.

Few studies have assessed changes in LV function and volume after removal of pericardial effusion in man,[7–9] and none have defined RV function and volume changes. Firestein et al[7] found that in patients with small pericardial effusion, LV end-diastolic diameter was not significantly altered. Grose et al[8] and Settle et al,[9] studying patients with large pericardial effusion, reported that LV dimensions were significantly smaller before removal of fluid. The results of these previous studies are complementary rather than discordant. If the amount of pericardial effusion is minimal and its rate of accumulation slow, its effects on LV volume will be minor. If the amount of effusion is large or its rate of accumulation fast, or both, LV filling and volume will be most compromised. We studied patients with and without cardiac tamponade and thus found a spectrum of end-diastolic volume changes. It should be noted that patients with small pericardial effusion function in the initial, flat portion of the intrapericardial pressure-volume curve, allowing a large volume change without significantly affecting the intrapericardiac pressure. In contrast, patients with cardiac tamponade function along the steep portion of the pressure-volume curve and small volume changes will significantly alter intrapericardial and diastolic LV transmural pressure.[12] In addition, slow accumulation of fluid will permit "stretching" of the pericardium,[13] lengthening the flat portion of the intrapericardial pressure-volume curve. Thus, the degree of LV end-diastolic volume change cannot be predicted by the amount of pericardial fluid removed. In our study, some of the most dramatic increases in end-diastolic volume were seen after removal of relatively small amounts of fluid, and in general, patients with cardiac tamponade showed the largest end-diastolic volume changes.

RV end-diastolic volume increased in our patients after removal of pericardial effusion. This finding was

not unexpected because left and right ventricles are enclosed in the pericardial sac and thus both chambers are subject to the same external pressure. When the intrapericardial pressure increases as a result of pericardial effusion, the shifts in diastolic transmural pressure and diastolic volume will be in the same direction in both ventricles. Changes in RV end-diastolic volume were relatively larger than those in the left ventricle, a finding likely related to the more compliant right ventricle.[14] This observation is in keeping with previous reports.[15]

The reason patients with normal LVEF showed larger increases in end-diastolic volume after pericardiocentesis than did those with subnormal EF is not clear. A decreased EF, which indicates impairment of ventricular performance, is by definition associated with a rightward shift of the LV function curve, and an elevated LV end-diastolic pressure is commonly found. At a given intrapericardial pressure, patients with elevated LV diastolic pressure will have a greater net filling pressure than will patients with normal LV end-diastolic pressure. Thus, it is possible that the greater net LV filling pressure of patients with low EF may "protect" the ventricle from the compressive effects of pericardial effusion. Because intracardiac or pericardial pressures were not measured in this investigation, we have no information to establish whether or not this mechanism was operational.

The effects of experimental pericardial effusion and cardiac tamponade on LV end-systolic volume and contractility are matters of controversy. Various indexes of myocardial contractility were reported to be impaired in some studies[1–4] but not in others.[5] However, studies in man show more consistent results. Firestein et al[7] reported no change in LV end-systolic diameter or parameters or systolic function, whereas Settle et al[9] detected a decrease in end-systolic diameter. As just discussed herein, these results are not contradictory but complementary, as they apply to patients with a small amount of effusion and patients with pericardial tamponade, respectively. Our results agree with these clinical studies[7,9] and with the recent findings of Grose et al.[8] Discrepancies between experimental and clinical studies are likely due to the fact that pericardial effusion is created over a period of minutes in animal studies, whereas effusion in man often accumulates over several days, weeks, or months. Our results further support the concept that inotropic agents and therapeutic interventions designed to change the pre- or afterload[16,17] may be of limited value in the treatment of cardiac tamponade. Recently, dopamine and isoproterenol were found to have marginal beneficial effects, probably because these agents were unable to significantly reduce the already extremely small end-systolic volume in these patients.[18] Similarly, increasing the preload and reducing the afterload produced limited and nonsignificant changes in right atrial pressure, arterial pressure, and cardiac output.[19]

Acute Effects of Phlebotomy on Right Ventricular Size and Performance in Polycythemic Patients With Chronic Obstructive Pulmonary Disease

ALLAN D. ERICKSON, MD, WILLIAM A. GOLDEN, MD, BEN C. CLAUNCH, MD, WALTER E. DONAT, MD, and JOHN T. KAEMMERLEN, MD

To assess the acute effects of phlebotomy on right ventricular size and performance, gated equilibrium radionuclide angiography was used to evaluate 10 patients with severe chronic obstructive pulmonary disease and erythrocytosis (hematocrit >55%). The mean right ventricular ejection fraction was abnormal before (0.38) but not after (0.43) phlebotomy, and the increase was highly significant ($p < 0.001$). Similarly, the right ventricular end-diastolic area decreased significantly from 588 to 505 pixels ($p < 0.02$). No significant changes occurred on the left side. Cardiac output was unchanged or slightly increased. Thus, assuming that afterload was unchanged, as reported by other investigators, the data herein are consistent with the hypothesis that a normalization in preload shifts the Starling curve, resulting in improved right ventricular performance with preservation of the cardiac output.

Severe chronic obstructive pulmonary disease (COPD) with its coexistent hypoxia, pulmonary hypertension, and occasional erythrocytosis, frequently leads to right-sided cardiac dysfunction. Although phlebotomy has been used for many years as therapy for the erythrocytosis seen in such patients, its short-term effects on right-sided heart size and performance have not been extensively investigated. Using a well-described gated equilibrium radionuclide angiographic method, we investigated the acute effects of venesection on right ventricular (RV) size and performance in 10 patients with severe COPD and erythrocytosis.

Methods

Patient selection: The study group consisted of 10 clinically stable men recruited from our pulmonary clinic, who were chosen because they had erythrocytosis (hematocrit >55%) secondary to COPD. No attempt was made to exclude patients with coexistent left heart disease, although no patient had clinical evidence of left ventricular (LV) failure (Table I). The mean age was 58 years. All patients had normal sinus rhythm. Eight patients had had carbon dioxide retention in the past and at least 7 had had episodes of RV failure. The control group consisted of 20 male physicians and staff who had no history of pulmonary or cardiac disease. The mean age was 40 years.

Procedures

On the day of radionuclide testing, all patients underwent spirometry with use of a Collins Vitalometer (Braintree, Massachusetts) as well as arterial blood gas determinations.

Radionuclide techniques: The patients were studied before and immediately after venesection of 350 to 500 ml. In vivo labelling of red blood cells with technetium-99m using the method of Pavel et al[1] was performed. Radionuclide angiography was carried out with a gamma camera (Dymax MB, Elscint, Hackensack, New Jersey) equipped with medium sensitivity, 30° slant hole collimator directed caudally to enhance separation of the ventricular and atrial blood pools. All studies were performed in the left anterior oblique projection, which gave optimal septal delineation. Gated images were acquired using a minicomputer (Digital Equipment 11/34, Maynard, Massachusetts) in a 64 × 64 matrix at a rate of 25 frames for each R-R interval, for a total of 7.5 million counts.

Data analysis: Using the method of Holman et al[2] and standard gamma camera computer software (Gamma 11), we generated a time-activity curve from a region circumscribing the estimated LV blood pool. The end-diastolic and end-systolic frames were chosen and 2 functional images were generated: the ventricular and atrial stroke volume images. The end-diastolic frame minus the end-systolic frame produced an image in which each pixel registered the change in counts between diastole and systole, which was proportional

FEV_1 = forced expiratory volume in 1 second (liters); H = hypertension; Hct = hematocrit; LV = left ventricular; PCO_2 = arterial carbon dioxide tension; PH = pulmonary hypertension; PO_2 = arterial oxygen tension; RV = right ventricular; RVE = right ventricular enlargement; RVH = right ventricular hypertrophy.

to ventricular volume change. Because of the phase difference between the atrial and ventricular volume curves, approximately 180°, subtraction of the end-diastolic image from the end-systolic image produced an atrial volume change image or paradox image. Superimposition of the ventricular and atrial stroke volume images resulted in a functional image which clearly delineated atrial and ventricular borders. With this composite image as a guide, we redefined the ventricular blood pools using a cursor. The ejection fraction (EF) for each ventricle was derived from another functional image: EF = (end-diastolic image − end-systolic image)/(end-diastolic image − background).

This method also included truncation of the superior aspect of the RVEF image in order to reduce atrial overlap and improve correlation with first-pass studies. The background was chosen automatically by an algorithm developed by Maddox et al[3] once the LV region had been approximated. Some operator discretion was permitted if background regions appeared inappropriate, such as over the spleen. Using this method, Holman found "excellent correlation between first pass and equilibrium studies in patients with both depressed and normal right ventricular function." His correlation coefficient was 0.95. The equilibrium RVEF was then corrected using the regression equation: $RVEF_{corrected} = 0.74\ (RVEF) + 0.03$.[2] The end-diastolic area was defined as the total number of pixels within the end-diastolic image, a reflection of ventricular volume that was independent of the concentration of radiolabel in the blood. A relative cardiac output was determined by multiplying the total number of counts contained in the LV region of the stroke volume image by the heart rate.[4]

Statistics: All group data are presented as means ± standard deviation. Student's *t* test for independent measures was used for comparison of groups. A *t* test for related measures was used to compare different studies performed in an individual patient. A p value <0.05 was considered significant.

Results

Spirometry and arterial blood gases: Results of spirometry (FEV_1) and arterial blood gas determinations performed at the time of radionuclide angiography are listed in Table I. The mean arterial oxygen tension in the patients breathing room air was 53 torr; 5 of the patients had an arterial carbon dioxide tension ≥45 torr.

Gated equilibrium radionuclide angiography: The mean RVEF among 20 normal control subjects was 0.48 ± 0.04. This was within 1% of Holman's normal control mean.[2] The mean resting RVEF of study patients before venesection was 0.38, significantly lower than the mean RVEF of normal control subjects (0.48), $p < 0.01$. The patient's mean RV end-diastolic area was 588 pixels, significantly higher than the control mean of 450, $p < 0.01$. The patients' mean LVEF was 0.59, which differed significantly from the control mean LVEF of 0.68 ($p < 0.05$). The patients' mean LV end-diastolic area of 777 was indistinguishable from the normal group mean of 686. Four of the 10 patients had a resting LVEF that was abnormal (<53%). Of those 4 patients, only 1 had clinical evidence of LV disease. All individual data are presented in Table II.

After the removal of 350 to 500 ml of blood, the patients' mean RVEF was 0.43 and RV end-diastolic area was 505 pixels; neither differed significantly from normal control values.

When the RVEFs in the study patients were compared before and after venesection, a significant increase was noted ($p < 0.001$). Similarly, when the pre- and postphlebotomy RV end-diastolic areas were compared, the ventricular size decreased significantly ($p < 0.02$) (Table II). No significant changes occurred on the left side. A relative cardiac output was calculated using the product of the total number of counts in the LV stroke volume image and the heart rate. The cardiac output did not change significantly after venesection. In order to assess the effects of radioactive decay and acute hemodilution on our cardiac output determination, we studied a single patient in the following manner. One ml of blood drawn during the prephlebotomy angiogram was counted in a gamma scintillation counter. It produced 6.37×10^6 counts/min immediately and 5.92×10^6 counts/min when recounted 30 minutes later during the postphlebotomy study. This 7% loss of ac-

ACO = cardiac output ($\times 10^6$ counts) when stroke volume counts increased by 12% to account for label decay and acute hemodilution; CO = cardiac output ($\times 10^6$ counts); EDA = end-diastolic area; EF = ejection fraction; LV = left ventricular; RV = right ventricular; SD = standard deviation.

tivity agrees well with the decay one would predict on the basis of a half-life of 6 hours. A second specimen of blood drawn during the postphlebotomy scan produced 5.60×10^6 counts/ml/min when counted immediately, which represents the 7% decay and some slight hemodilution (the hematocrit decreased from 57% to 56%). If one assumes a similar time interval and degree of acute hemodilution for all the patients and increases the stroke volume counts in each postphlebotomy study by 12%, a small but statistically significant increase in cardiac output is then seen (Table II). The EF and end-diastolic area calculations are independent of radiolabel concentration.

Intraobserver variability: All data analysis was performed by 1 individual and repeat determinations varied by <2%.

Discussion

Although first-pass radionuclide angiography has been used by several investigators[5–8] to evaluate RV performance in patients with COPD, equilibrium radionuclide studies in such patients are just beginning to be reported.[9,10] In general, these investigators found that one third to one half of patients with severe COPD have a decreased RVEF at rest and many have an abnormal response to exercise. In general, the principal difficulty with equilibrium methods has been the problem of right atrial and ventricular overlap. We attempted to solve the problem of chamber overlap by use of functional images to define the perimeter of the RV end-diastolic region of interest and by truncation of the superior aspect of the EF image which consists largely of infundibulum and pulmonary artery.[2]

There are limited data available concerning the acute effects of phlebotomy on RV size and performance in polycythemic patients with COPD. Using an indicator dilution technique, Schaanning and Sparr[11] described a significant decrease in the cardiac output of polycythemic COPD patients after venesection of 500 ml. In contrast, Gertz et al[12] described no change in pulmonary arterial pressure, pulmonary vascular resistance, RV end-diastolic pressure, or cardiac output after venesection in 6 patients with similar disease. They concluded that the only demonstrable change after venesection was a slight increase in the heart rate and a decrease in the arterial carbon dioxide tension. Similarly, Rakita et al[13] described the acute hemodynamic changes after venesection in COPD patients and concluded that the right atrial and RV end-diastolic pressures decreased significantly, but that there was no change in cardiac index, pulmonary arterial pressure, or pulmonary vascular resistance.

In our 10 patients, venesection produced an increase in RVEF (0.38 to 0.43, $p < 0.001$) and a decrease in the RV size (RV end-diastolic area 588 to 505, $p < 0.02$). Cardiac output did not decrease. If one assumes, as was found by Gertz,[12] Rakita,[13] and their co-workers, that venesection causes no acute decrease in the pulmonary arterial pressure, that is, afterload or pulmonary vascular resistance, our data are consistent with the hypothesis that a normalization in preload shifts the Starling curve, resulting in an increased RVEF with the preservation or improvement of the cardiac output. Brent et al,[14] using hemodynamic and first-pass radionuclide methods, recently documented that RVEF is determined in part by preload. We conclude that venesection produces favorable short-term hemodynamic changes in patients with severe COPD and erythrocytosis, although the duration of this effect is unknown.

Left Ventricular Performance During Exercise: Response of Ear Densitogram Derivative

BRUCE G. HAFFTY, MS, TETSURO SUGIURA, MD, NANCY E. O'HARE, MS, and DAVID H. SPODICK, MD, DSc

The peak derivative of the ear densitogram (PD) has been shown to track left ventricular (LV) function during exercise. Measured as percent change in amplitude from resting control, PD in normal subjects slowly and consistently increased throughout exercise and to 2 minutes of recovery, followed by return to control level. In contrast, PD in patients with coronary artery disease rapidly increased only to 1 minute of exercise, with no significant subsequent increase. Expressed as a percent change from control, the response of normal subjects differs significantly from that of patients with coronary artery disease at 1 and 4 minutes of exercise, and 2 minutes of recovery. The PD increase in normal subjects from end-exercise to 2 minutes of recovery may be attributable to the heart rate decreasing faster than venous return, associated with LV ejection time, which is significantly shorter than heart rate-predicted values 2 minutes after exercise.

Several studies have shown the first derivative of peripheral pulse waves to be a reliable correlate of left ventricular (LV) function.[1–6] The first derivative of the aortic and brachial pressure curves and the carotid pulse have all been used to track cardiac function under various hemodynamic conditions. Recently, Nakamura et al[7] showed that the peak of the first derivative of the ear densitogram (PD) tracked several indexes of LV function including ejection rate, ejection fraction, stroke volume, and velocity of circumferential fiber shortening in patients with atrial fibrillation. In the cardiac catheterization laboratory we also have shown that changes in PD correlate well with changes in ejection rate.[8] Along with several previous studies in which the ear densitogram signal has proved very stable and reliable for monitoring systolic time intervals during all levels of exercise,[9–12] these results demonstrated that the PD can be used to continuously track global function throughout exercise.

The ear densitograph has several advantages for continuous (including beat-to-beat) physiologic monitoring[13]: (1) it is stable during conditions tending to produce motion artifact; (2) it is reproducible; (3) the sensor's application pressure is always the same; and (4) it is totally noninvasive, safe, and inexpensive. This study was designed to characterize the response of the PD to uninterrupted treadmill exercise in normal subjects and coronary patients, and to evaluate its use as an adjunctive method in exercise testing.

Methods

Subjects: We investigated the response of the ear densitogram in 2 groups of subjects. Group I consisted of 13 men, 5 with normal coronary angiograms and 8 normal volunteers, who fulfilled 2 criteria: (1) normal history, physical examination, chest x-ray film, and electrocardiogram; and (2) negative exercise test (completed maximum Bruce protocol). Group II consisted of 8 men found to have >50% narrowing of at least 1 major coronary artery, who fulfilled 2 criteria: (1) none had myocardial infarction, valvular disease, or coronary surgery; and (2) none was taking any cardiac medication.

The small number of patients in this study was predictable because of the strict criteria requiring only patients who had undergone coronary angiography and were not taking any medication and the time frame (9 months) available (almost every patient undergoing angiography receives 1 or more medications). Of 738 consecutive patients referred during 9 months for electrocardiographic stress testing, this yielded only 17 men, 10 with >50% narrowing of at least 1 coronary artery and 7 with normal coronary angiograms. We were able to obtain recordings of the ear densitogram throughout all levels of exercise and recovery in 5 of the 7 subjects with normal coronary angiograms and 8 of the 10 patients with coronary artery disease. Although symptomatic patients with

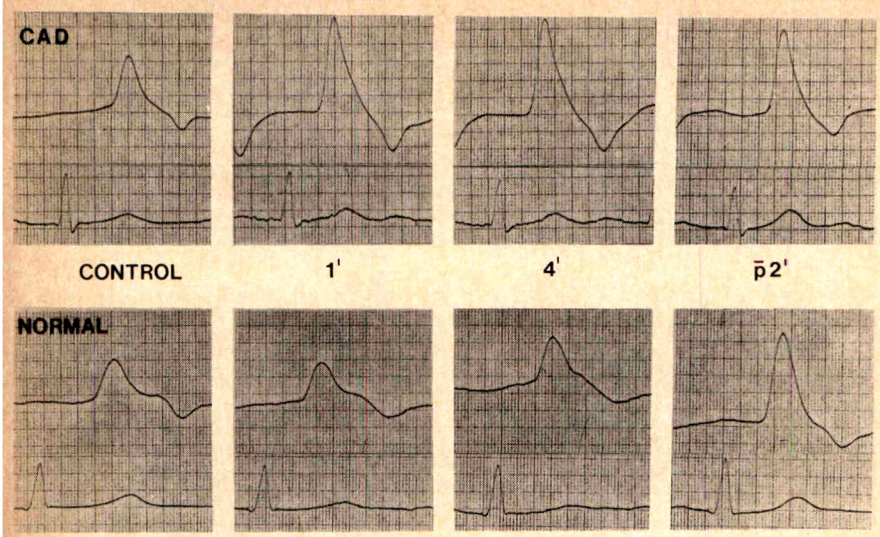

FIGURE 1. Representative densitogram traces from a patient in each group. **Top,** coronary artery disease (CAD). **Bottom,** normal subject. The times represented are control times and those times at which the results showed significant differences in mean responses between groups: 1 minute and 4 minutes of exercise and 2 minutes after exercise ($\bar{p}$ 2′).

normal angiograms may not be normal in the strictest sense, the results of noninvasive testing (exercise tests and systolic time intervals) in the 5 patients noted were also indistinguishable from those of 8 normal volunteers; these data were therefore consolidated for analysis.

The test was performed on a Quinton 18-54 treadmill without interruption at speeds of 1.7, 1.7, 2.5, 3.4, 4.2, and 5.0 mph; corresponding elevations were 5, 10, 12, 14, 16, and 18% (the first stage was 1 minute and all other stages were 3 minutes). The test was considered positive when there was ≥1 mm horizontal or downsloping S-T depression 80 ms after the QRS complex in 3 consecutive beats, and negative when the subject achieved >90% age-predicted maximal heart rate without that change.

The PD was obtained by filtering the signal from the ear densitogram (Hewlett-Packard model 780-16 earpiece, attached to the pinna of the ear as previously reported in detail)[13] through a Hewlett-Packard 7712 preamplifier with the low frequency cutoff set at 15 Hz. Recordings were made on a Cambridge model 3044B 3-channel stress test system at 100 mm/s. Control measurements were made after standing for 2 minutes. Subsequent recordings were made as patients were completing each stage. The end-exercise tracing was recorded immediately after exercise with the subject in the sitting position, as were the recovery recordings at 2, 5, and 10 minutes after exercise.

The measurements for obtaining heart rate, systolic time intervals, and the PD amplitude were aided by use of a Summagraphics digitizer coupled to a DEC-90 computer, with use of a program developed in this laboratory. Data were calculated from the mean of 5 consecutive beats for each recording as previously reported in detail.[13]

All statistical analyses were performed on the DEC-20 computer using the Bio Medical Data Program statistical package developed at UCLA.

Results

All patients in Group II and the 5 subjects with normal coronary angiograms in Group I had had chest pain consistent with angina pectoris. All 5 of those who proved to have normal coronary angiograms had negative maximum exercise tests (Bruce protocol). Results of exercise testing in Group II showed that only 3 of the 8 patients were judged to have a positive exercise test (2 mm S-T depression or elevation at 0.08 second after the end of the QRS complex) at end-exercise. One of these 3 patients had positive findings at 1 and 4 minutes of exercise with the test thereafter terminated. Of the other 2, 1 had negative findings at 1 minute and 4 minutes and the other showed 1 mm S-T elevation at 4 minutes, though negative at 1 minute. The other 5 patients in Group II had negative tests at 1 minute, 4 minutes, and at end-exercise.

Figure 1 shows representative densitographic curves in a patient in each group at the times when responses were statistically different, that is, at 1 and 4 minutes of, and 2 minutes after, exercise. Measurements of heart rate, preejection period, LV ejection time, and PD from control through the recovery period for Groups I and II are given in Table I. Except for differences at the end of exercise, the heart rate responses of Groups I and II are similar.

There were no significant differences in the control values of PD in the 2 groups. The normal group showed a slight but insignificant increase in PD at 1 minute of exercise, whereas the group with coronary artery disease showed a significant increase at 1 minute of exercise. When expressed as a percent change from control, the response of PD in the control group was significantly less than that of the coronary artery disease group at 1 minute of exercise ($p < 0.01$).

In all subsequent stages of exercise the normal group showed significant increases in PD. During recovery the normal group showed a further increase in PD from end-exercise to 2 minutes after exercise, followed by significant decreases toward control at 5 and 10 minutes after exercise.

Except for the increase in PD from control to 1 minute, the group with coronary artery disease showed only slight, insignificant increases throughout all subsequent stages of exercise. From end-exercise to 2 minutes after exercise, the PD showed no significant change in the coronary artery disease group. PD then decreased toward control values at the 5- and 10-minute postexercise levels. The 10-minute postexercise PD values for

both groups were not significantly different from control. The response of PD for each group is given in Table II. The p values indicate levels of significance for changes from the preceding stage. Figure 2 shows the percent change in PD from control throughout exercise in each group, and levels of significance for differences between groups.

Discussion

The PD appears to be a useful clinical tool for tracking LV function throughout exercise. The greater increase in PD from control in patients with coronary artery disease than in normal subjects at 1 minute of exercise is consistent with our previous report that the preejection period/LV ejection time (LVET) showed a greater reduction in abnormal than in normal subjects at 1 and 4 minutes of exercise.[10] These data are also consistent with the observations of Vatner et al,[14] who found initial improvement in LV function during exercise in dogs with coronary occlusion.

Other studies, demonstrating marked increase in end-diastolic pressure[15] and higher plasma levels of catecholamines[16] during exercise in patients with coronary artery disease, may explain this increased function observed in early exercise. Whatever the mechanism, the data presented indicate that the response of PD in early exercise tends to separate the control group from the coronary artery disease group.

Coronary angiography in the coronary artery disease group showed 2 with 3-vessel disease, 3 with 2-vessel disease, and 3 with 1-vessel disease. As judged by S-T segment response, 1 patient in each group had positive findings (with 1 of the patients with 2-vessel disease being the only subject who had positive findings at 1 and 4 minutes of exercise). Because of the necessarily small

TABLE III Recovery Period Ejection Times in 13 Normal Subjects

numbers (for reasons given previously) of such patients, who despite angiography had no medication, expressions of sensitivity and specificity might be deceptive and we are reluctant to state cutpoints. Until we have larger numbers this report may be considered preliminary, documenting *trends* for this promising method (Fig. 2). Moreover, the pulse derivative cannot be individually calibrated at present so that these are relative changes. The largest such changes were seen at 1 minute ($p < 0.01$), at which time 7 of the 8 patients in Group II had mean values of percent change in PD of from 2 to $10\frac{1}{3}$ times the respective means in the normal subjects (Group I). Patient 8 deviated from Group I only at 2 minutes after exercise, when his percent change in PD was one half the normal mean.

In the normal group the continuous increase in PD throughout exercise is consistent with the expected increases in measurements shown to be correlates of PD: ejection rate, stroke volume, and contractility indexes reported in several other studies.[17–19]

The supplemental normal subjects were added to those with normal angiograms (Group I) on the basis of absence of history, physical examination, and electrocardiographic and stress test evidence of heart disease. Because they could not have undergone angiography, we have no absolute knowledge that some did not in fact have coronary lesions. However, on the basis of the noninvasive matching, they performed identically to the patients with chest pain and normal angiograms.

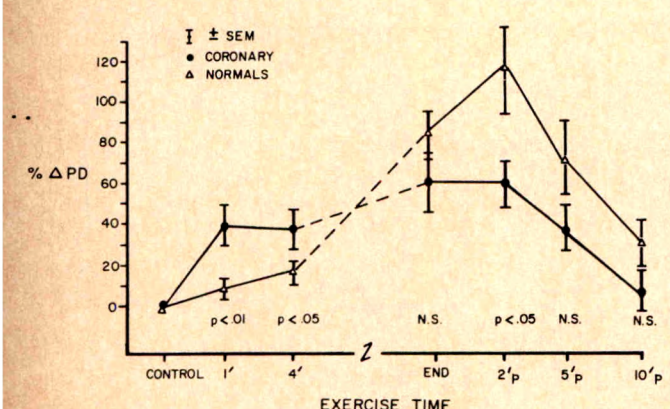

FIGURE 2. Trend chart showing changes from control as percent increases and decreases in peak derivative (% ΔPD). Mean differences are statistically different between patients with coronary artery disease (**black dots**) and normal subjects (**triangles**) at 1 minute and 4 minutes of exercise and 2 minutes after exercise.

Therefore, we are confident in supplementing Group I in that way. We have additional confidence in that method because each of these patients completed the Bruce protocol to individual maximum heart rate targets, whereas 7 of the 8 with positive angiograms could not achieve that.

The increase in PD from end-exercise to 2 minutes after exercise appears consistent with investigations reporting increased cardiac function in the recovery period. Cumming[20] noted an increase in stroke volume from peak exercise to 2 minutes after exercise. Reindell et al[21] postulated increased cardiac function 2 minutes after exercise based on increase in ratios of oxygen uptake to heart rate in the postexercise period. Stein et al,[22] using echocardiography, found increased end-diastolic volume and greater fractional fiber shortening during the recovery period, and Horowitz et al[23] noted an increased end-diastolic diameter during recovery from severe treadmill exercise in dogs. All these investigators conclude that the heart rate decreased faster than venous return during the recovery period, attributable to a classic Frank-Starling mechanism.

In the normal subjects the increase in PD from end-exercise to 2 minutes after exercise was associated with a decrease in the expected LVET, based on the standard regression equation LVET = 374 − 1.2 heart rate.[12] When differences between expected and observed LVETs were compared, the 2-minute postexercise LVET was consistently and significantly shorter than its predicted value, whereas the end-exercise and the 5-minute and 10-minute postexercise LVETs were not significantly different from expected values (Table III). Because all recovery recordings were made in the sitting position, this could not be a positional effect.

Because the 2 determinants of LVET are stroke volume and ejection rate, the disproportionately short LVET would indicate that either stroke volume is decreasing or ejection rate is increasing disproportionately from end-exercise to 2 minutes after exercise. The increased PD, which we have previously shown to correlate with ejection rate,[7] indicates that the latter phenomenon is most likely.

This increase in function, associated with a disproportionately short LVET in the postexercise period, would be a physiologically desirable response in that cardiac output would be maintained to meet metabolic demands, whereas the ventricles spend relatively less time in systole, thereby decreasing oxygen demand.

The coronary artery disease group showed no significant increase in PD from end-exercise to 2 minutes after exercise, nor was the difference between expected

and observed LVET 2 minutes after exercise significantly different from the other recovery period recordings. Comparisons between the 2 must be judged with caution, however, because of (1) the predictable individual differences in end-exercise times and end-exercise heart rates, and (2) the necessarily small groups owing to the rigid inclusion and exclusion criteria, that is, 17 (of 738 consecutive subjects) who had undergone arteriography but had no medication. More cases, including subgroups of patients with coronary artery disease, will be needed to extend this study from a pilot investigation and refine the clinical use of this postexercise response of PD.

Effect of Cimetidine on the Pharmacokinetics and Pharmacodynamics of Quinidine

BRIAN G. HARDY, PharmD, ISTVAN T. ZADOR, MD, LAWRENCE GOLDEN, MD, DAVID LALKA, PhD, and JEROME J. SCHENTAG, PharmD

The influence of cimetidine (1.2 g/day for 7 days) on the disposition and pharmacodynamic effects of a single oral dose of quinidine was studied in 6 normal volunteers. Cimetidine reduced the mean apparent oral clearance of quinidine (± standard error of the mean) from 25.5 ± 2.7 to 16.2 ± 1.4 liters/h ($p < 0.05$). This was reflected in a 55% (range 30 to 109) increase in the mean half-life from 5.8 ± 0.2 to 9.0 ± 0.6 hours ($p < 0.05$). Peak quinidine plasma concentrations and times to peak were also increased ($p < 0.05$). Plasma protein binding and urinary excretion of quinidine were unchanged by cimetidine treatment. Alterations in the pharmacokinetic variables of quinidine were mirrored in simultaneously measured electrocardiographic parameters. Changes in Q-T, rate-corrected Q-T, QRS, and R-R intervals after a single oral dose of quinidine sulfate (400 mg) were significant. Treatment with cimetidine potentiated these pharmacodynamic changes, but failed to achieve significant differences from quinidine alone. Thus, cimetidine impairs the elimination of oral quinidine in normal volunteers. This interaction may lead to quinidine toxicity in patients in whom cimetidine is concomitantly administered.

Cimetidine has gained widespread use in the treatment of peptic ulcer disease, with sales exceeding $500 million annually.[1] The extensive use of this H_2-receptor antagonist reflects the relatively infrequent and minor adverse effects observed in patients with normal renal and hepatic function.[2] However, recently cimetidine has been shown to reduce liver blood flow[3] and impair hepatic clearance of drugs such as warfarin,[4] benzodiazepines,[5] theophylline,[6] propranolol,[3] phenytoin,[7] and lidocaine.[8] This interaction has potential clinical significance for those drugs with a narrow therapeutic index, extensively cleared by hepatic metabolism.

Quinidine is an effective oral antiarrhythmic agent widely used in the management of various chronic disorders of cardiac rhythm. Unfortunately, the drug has a narrow therapeutic index, which clinically means that life-threatening arrhythmias are uncontrolled at subtherapeutic concentrations and severe toxicities manifest at only 2 to 3 times the minimum effective concentration.[9] Quinidine is metabolized by the liver to (3S)-3-hydroxyquinidine, 2′-oxoquinidinone, O-desmethylquinidine, and a metabolite tentatively identified as a rearrangement of quinidine-N-oxide.[10] The relative contribution of each biotransformation pathway to the overall removal of quinidine by drug metabolism is not yet known. The 3-hydroxyquinidine and 2′-oxoquinidinone metabolites have been shown to possess antiarrhythmic potencies comparable to those of the parent compound.[11] Less than 10 to 25% of a given quinidine dose is excreted unchanged.

As quinidine is largely eliminated by hepatic biotransformation, it is potentially subject to interventions that alter liver metabolic activity. Phenobarbital, phenytoin, and rifampin, all potent enzyme inducers, have been shown to at least double the rate of elimination of quinidine.[12,13] To date, no drug has been shown to decrease the clearance of quinidine by metabolic inhibition. However, pathophysiologic changes associated with congestive heart failure, such as reduced blood flow, have resulted in reduced quinidine clearance[14] and increased toxicity.[15]

In view of the implications of quinidine toxicity, it appeared reasonable to establish whether a significant drug interaction exists between quinidine and cimetidine.

From the Department of Pharmaceutics, Division of Clinical Pharmacy Science and the Department of Medicine, Schools of Pharmacy and Medicine, State University of New York at Buffalo, and the Clinical Pharmacokinetics Laboratories of Buffalo General Hospital and Millard Fillmore Hospital, Buffalo, New York. This study was supported in part by National Institute of General Medical Sciences Grant 20852 from the National Institutes of Health, Bethesda, Maryland. Manuscript received November 26, 1982; revised manuscript received and accepted March 18, 1983.

Address for reprints: Jerome J. Schentag, PharmD, Clinical Pharmacokinetics Laboratory, Millard Fillmore Hospital, Buffalo, New York 14209.

Methods

Six healthy male volunteers (aged 25 to 38 years) consented in writing to participate in the study, which was approved by the University and Institutional Review Committees. Volunteers were screened for normal health by medical history, physical examination (including prestudy electrocardiograms), and clinical laboratory testing (complete blood count with differential, platelet count, serum electrolytes, total bilirubin, alkaline phosphatase, serum transaminases, lactic dehydrogenase, glucose, total protein, blood urea nitrogen, serum creatinine, and urinalysis). Volunteers were nonsmokers and social users or nonusers of alcohol, with no known hypersensitivity to cimetidine or quinidine. They were asked to abstain from drinking alcoholic beverages during the course of the study.

The volunteers fasted for 8 hours before and 3 hours after quinidine administration. On the first day of the study, an oral dose of 400 mg quinidine sulfate (as two 200 mg tablets) was administered to each volunteer with approximately 100 ml of water. This dose is equivalent to about 330 mg of quinidine base. A total of 15 blood samples (5 ml each) were obtained at 0, 0.25, 0.5, 1.0, 1.5, 2.0, 2.5, 3, 4, 5, 6, 8, 10, 12, and 24 hours after drug administration. A continuous intravenous drip with 5% dextrose solution was used to keep the forearm angiocath patent. Blood samples were collected in screw-top glass vials; the plasma was separated within 2 hours and stored at −20°C until assayed (Syva-Emit®). On the third day, the volunteers began a 7-day course of oral cimetidine, 300 mg 4 times daily. On the eighth day, a second 400 mg quinidine sulfate dose was administered and blood collections obtained as per day 1. Complete 48-hour urine collections were obtained after quinidine administration and the pH was determined. Urine aliquots were assayed for quinidine by high-pressure liquid chromatography.[16]

Plasma protein binding of quinidine was determined by equilibrium dialysis of plasma from quinidine-free volunteers against a 0.143 M phosphate buffer, titrated to pH 7.4, containing 1.25 μg/ml of H^3-quinidine (purified to >98% by thin-layer chromatography) (New England Nuclear, Boston, Massachusetts). In vitro binding of H^3-quinidine was measured in plasma samples obtained before and after a 5-day course of cimetidine. Plasma $alpha_1$-acid glycoprotein concentrations were measured on both study days by radial immunodiffusion (Calbiochem-Behring, La Jolla, California).

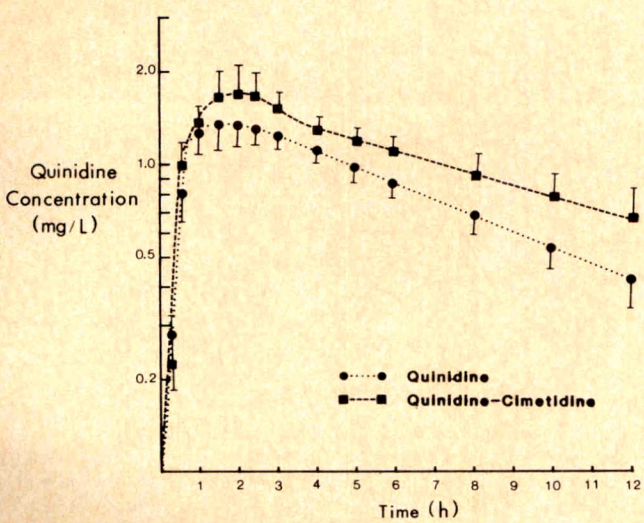

FIGURE 1. Plasma quinidine concentration-time profiles for mean (± standard error of the mean) data obtained after oral doses of 400 mg of quinidine sulfate in 6 normal volunteers with (**squares**) and without (**circles**) cimetidine treatment, 1.2 g daily for 7 days.

TABLE I Effect of Cimetidine on the Pharmacokinetics of Quinidine in 6 Normal Volunteers

	Without Cimetidine	With Cimetidine
Apparent oral clearance (liters/h)	25.5 ± 2.7	16.2 ± 1.4*
Elimination half-life (hours)	5.8 ± 0.2	9.0 ± 0.6*
Peak concentration (mg/liter)	1.5 ± 0.2	1.8 ± 0.2*
Time to peak (minutes)	91 ± 17	121 ± 15*
Unbound in plasma (%)	15.1 ± 0.7	15.1 ± 0.6
$Alpha_1$-acid glycoprotein (mg/dl)	74 ± 5	75 ± 4
Urinary excretion (%)	22.1 ± 1.6	22.4 ± 2.3

Values are expressed as means ± standard error of the mean.
* Significantly different ($p < 0.05$) from quinidine alone.

The electrocardiogram was monitored before and continuously after quinidine administration. Holter recordings were marked at all blood collection time points. During both control and study periods, QRS, R-R, and Q-T intervals were measured by a cardiologist blinded to the coded recordings. Interval values represent the average measurement of 5 sequential QRS complexes. The Q-T interval was corrected for heart rate (Q-Tc) according to the formula Q-Tc = Q-T measured/$\sqrt{\text{R-R}}$.[17] Blood pressures were obtained frequently during the first 4 hours and at 2 time points thereafter. Volunteers were asked to report any subjective effects (for example, dizziness, diarrhea, headache) felt to be associated with administration of quinidine or cimetidine.

The area under the plasma concentration-time curve after oral administration (AUC_o) of quinidine was extrapolated to infinity using the model-independent computer program LAGRAN. This program determines the areas and moments of plasma concentration-time data using the Lagrange technique[18] alone or in conjunction with linear or log-trapezoidal methods. The apparent oral clearance (Cl_o) was estimated using the formula Cl_o = dose/AUC_o. Since sampling around the peak was frequent, the highest value in the plasma concentration profile was used to represent the peak concentration (C_{max}). The time to reach this peak concentration was denoted T_{max}. Whereas AUC_o, Cl_o, C_{max}, and T_{max} were estimated essentially by model-independent means, the half-life was determined by nonlinear regression of the terminal phase of the plasma concentration-time profile.

The area under the electrocardiographic parameter change (such as ΔQ-Tc, ΔQRS) versus time curve was calculated for each volunteer from 0 to 12 hours by the linear trapezoidal method. Concentration-response profiles for quinidine, with and without cimetidine, were obtained by plotting the mean area under the change in Q-Tc versus time curve (ΔQ-Tc AUC) against the area under the plasma quinidine concentration-time curve (concentration AUC) as integrated for each blood collection interval.

Statistical comparisons were made using the paired Student's *t* test and linear regression analysis. The minimal level of significance was defined as $p < 0.05$.

Results

The mean quinidine plasma concentration-time profiles, with and without cimetidine treatment, are illustrated in Figure 1. After cimetidine treatment, statistically significant increases in quinidine elimination half-life of 55% (range 30 to 109), C_{max} of 21% (range 8 to 61), and T_{max} of 33% (range 8 to 118) were observed.

For each subject, the area under the oral quinidine plasma concentration-time profile was greater after treatment with cimetidine. This resulted in a decrease in mean Cl_o of 37% (range 23 to 49) from 25.5 ± 2.7 to 16.2 ± 1.4 liters/h ($p < 0.05$). The plasma protein binding of quinidine, plasma alpha$_1$-acid glycoprotein concentrations, and the percent urinary recovery of unchanged quinidine were unaffected by cimetidine treatment. These data are listed in Table I.

The alterations in pharmacokinetic variables were accompanied by increases in pharmacodynamic responses, although these differences failed to achieve statistical significance. The mean changes (± standard error of the mean) in Q-Tc after oral quinidine administration with and without cimetidine, are shown in Figure 2. Without cimetidine, the mean area under the Q-Tc change versus time curve (ΔQ-Tc area) was 576 ± 101 ms·h, demonstrating a notable prolongation of the rate-corrected Q-T time after a single oral quinidine dose. With cimetidine treatment, the mean ΔQ-Tc area increased 28% to 727 ± 78 ms·h. Similarly, the mean ΔQ-T area increased 51% from 362 ± 56 to 545 ± 71 ms·h, the mean R-R area was 9,443 ± 378 ms·h before and 9,335 ± 370 ms·h after cimetidine therapy, and the mean ΔQRS area was 40 ± 10 ms·h before and 37 ± 12 ms·h with the addition of cimetidine.

A pooled concentration-response curve for quinidine, with and without cimetidine, is illustrated in Figure 3. A strong relationship between quinidine plasma concentration AUC and ΔQ-Tc AUC was observed with ($r = 0.989$) and without cimetidine ($r = 0.965$). Cimetidine treatment did not shift the concentration-response profile of quinidine, as the slopes (65.9 ± 3.0 versus 62.3 ± 5.1, ms·liter/mg) and intercepts (−5.4 ± 3.3 versus −4.6 ± 4.5 ms·h) with and without cimetidine, respectively, were not statistically different. However, after cimetidine treatment, higher plasma quinidine concentrations were achieved with equivalent quinidine dosage. This resulted in predictable increases in ΔQ-Tc.

All volunteers had a transient decrease in mean blood pressure (10 to 30 mm Hg), 2 volunteers had diarrhea from quinidine, and 1 subject had headaches while taking cimetidine.

Discussion

When a drug with a low hepatic extraction (for example, Cl_o <6 liters/h) is administered either intravenously or orally, elimination depends mainly upon intrinsic hepatic clearance. The inhibition of low clearance drugs by cimetidine has been previously described for warfarin,[4] diazepam,[5] theophylline,[6] and phenytoin.[7] Low clearance drugs are relatively insensitive to changes in hepatic blood flow, whereas high clearance drugs (for example, Cl_o >240 liters/h) are perfusion rate-dependent. Alterations in hepatic metabolism influence high clearance drugs after oral administration (first-pass effect), but not after intravenous administration. However, cimetidine has been demonstrated to decrease the clearance of intravenously administered high

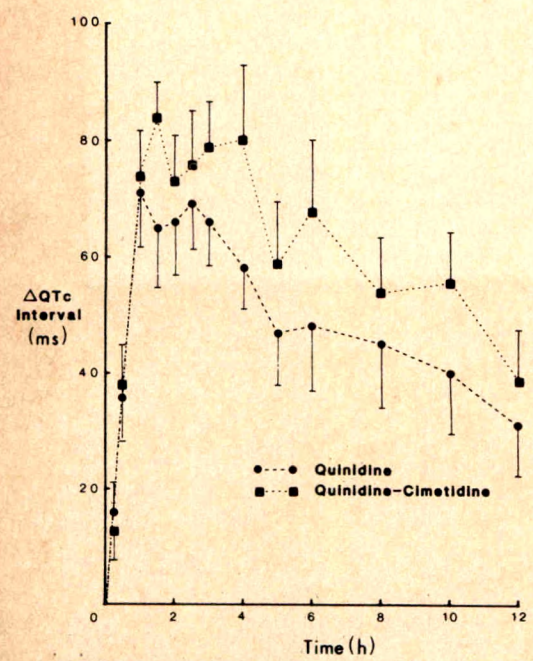

FIGURE 2. Effect of cimetidine on the pharmacodynamics of quinidine. Values represent the mean (± standard error of the mean) change in rate-corrected Q-T time obtained after a single oral dose of 400 mg quinidine sulfate in 6 normal volunteers with **(squares)** and without **(circles)** cimetidine treatment, 1.2 g daily for 7 days.

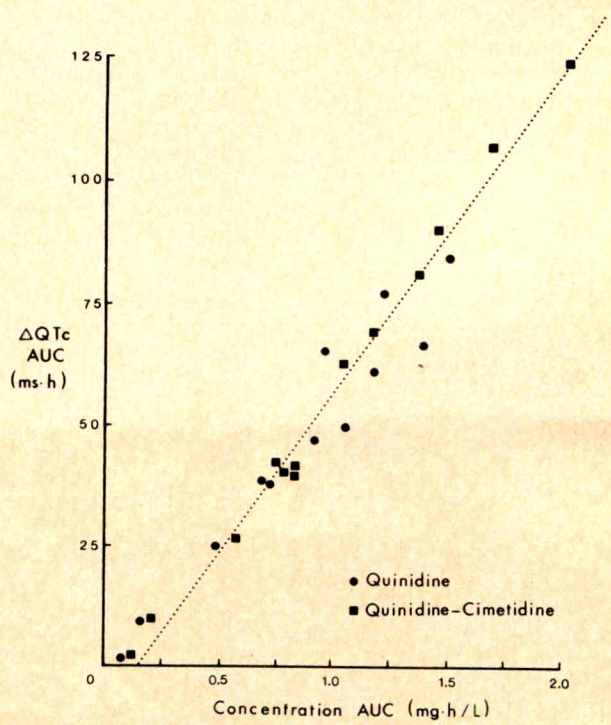

FIGURE 3. Effect of cimetidine on the concentration-response curve of quinidine. Values represent the mean data for area under the change in Q-Tc versus time curve (ΔQ-Tc AUC) as plotted against the area under the plasma quinidine concentration-time curve (concentration AUC) integrated between each blood collection time point. A strong correlation between concentration and response was observed with **(squares)** ($r = 0.989$) and without **(circles)** ($r = 0.965$) cimetidine treatment. Slopes and intercepts remained unchanged after cimetidine treatment (see text).

clearance drugs such as propranolol[3] and lidocaine.[8] This effect may be partially explained by cimetidine-induced reduction in hepatic blood flow.[3] In the case of lidocaine, a reduction in volume of distribution was observed.[8]

The mean apparent oral clearance of quinidine was 25.5 liters/h in our normal volunteers. Although quinidine is a relatively low extraction drug, factors that alter hepatic perfusion cannot be totally ignored. The higher peak concentrations of quinidine and the delay in the time to achieve these peak concentrations after cimetidine treatment may be related to hepatic enzyme inhibition, reduced liver blood flow, or both. Furthermore, an increase in quinidine absorption in the presence of cimetidine cannot be excluded as a possible explanation for the observed elevations in quinidine plasma concentrations.

Regardless of the specific pharmacokinetic mechanisms involved, elevations in plasma quinidine concentrations are presumably associated with corresponding increases in myocardial tissue concentrations at steady state. Clinically, this is reflected in changes in electrocardiographic parameters which are known to be sensitive indicators of quinidine activity.[19] In our study, there was an observed increase in mean area under the Q-T and Q-Tc change versus time curves of 50 and 28%, respectively, after coadministration of cimetidine and quinidine. This suggests that alterations in quinidine pharmacokinetics by cimetidine are mirrored by changes in quinidine pharmacodynamics. The concentration-response curve for quinidine was unchanged in the presence of cimetidine (Fig. 3). This implies the observed increases in the pharmacodynamic effects of quinidine were the result of increased plasma quinidine concentrations and not due to any direct effect of cimetidine or its metabolites on the myocardium.

Cimetidine alters the disposition of oral quinidine in normal volunteers. Although multiple dose studies in patients are desirable, it is not unreasonable to postulate that similar changes may occur in patients stabilized on chronic oral quinidine when cimetidine therapy is initiated. This drug interaction may also predispose patients to the proarrhythmic effects of quinidine. Malignant arrhythmias such as ventricular tachycardia and fibrillation have been observed in quinidine-treated patients after marked Q-T prolongation.[20] In view of the existing potential for enhanced pharmacologic activity, these patients may require initial observation for early signs of quinidine toxicity as monitored by quinidine levels, frequent electrocardiographic monitoring, and clinical assessment.

Acknowledgment: We are grateful to David Edwards and Kevin Gipple for their technical assistance, and to Richard Slaughter for his assistance with the concentration-response analysis.

*"Simplifying drug regimens is one method of improving patient compliance."**

SEARLE Aldactazide®

(spironolactone 50 mg/hydrochlorothiazide 50 mg)

50/50 q.d.

Uncomplicated, once-a-day dosage
Increased convenience for increased compliance.

Fewer tablets to swallow
A compliance advantage for patients presently on Aldactazide 25/25 therapy—especially when they are taking several medications.

Film-coated tablets
Easy to swallow with no unpleasant taste.

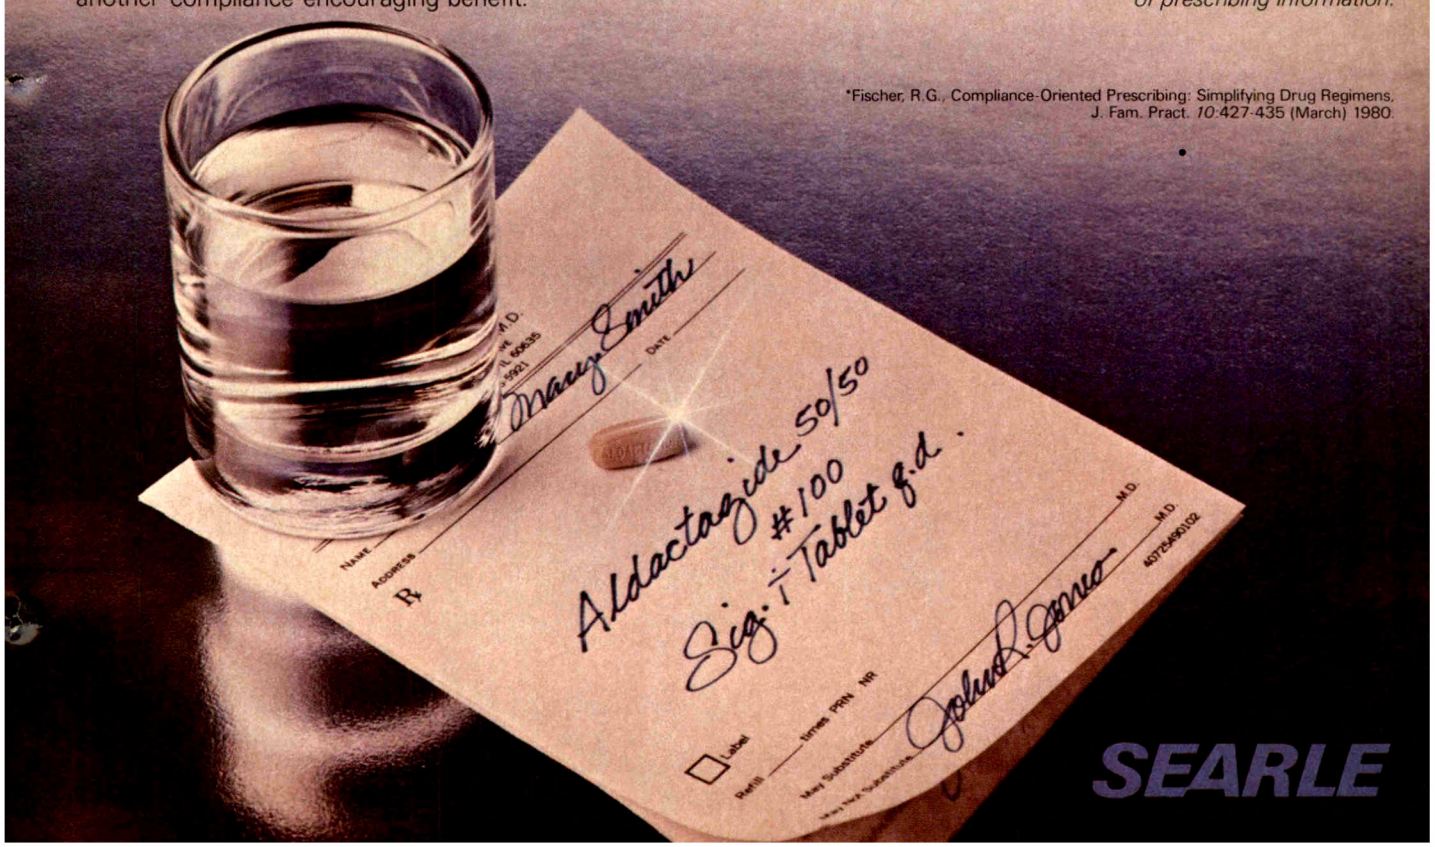
Helps regulate potassium
Ordinarily no need for potassium supplements—another compliance-encouraging benefit.

Now available—a single-tablet once-a-day dosage to encourage patient compliance

Established efficacy
Aldactazide is a recognized antihypertensive agent for effective, long-term control of hypertension when other measures are considered inadequate or inappropriate.

Limitations to consider
Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. Thus, Aldactazide should be prescribed only when other measures are considered inadequate or inappropriate. (See boxed warning and *Warnings* section of Aldactazide prescribing information.)

Please see next page for a brief summary of prescribing information.



*Fischer, R.G., Compliance-Oriented Prescribing: Simplifying Drug Regimens, J. Fam. Pract. *10*:427-435 (March) 1980.

Aldactazide®

(spironolactone 50 mg/hydrochlorothiazide 50 mg)

WARNING:
Spironolactone, an ingredient of Aldactazide, has been shown to be a tumorigen in chronic toxicity studies in rats (see *Warnings*). Aldactazide should be used only in those conditions described in the *Indications* section of the complete prescribing information. Unnecessary use of this drug should be avoided. Fixed-dose combination drugs are not indicated for initial therapy of edema or hypertension. Edema or hypertension requires therapy titrated to the individual patient. If the fixed combination represents the dosage so determined, its use may be more convenient in patient management. The treatment of hypertension and edema is not static, but must be reevaluated as conditions in each patient warrant.

Contraindications: Anuria, acute renal insufficiency, significant impairment of renal function, hyperkalemia or acute or severe hepatic failure. Allergy to thiazide diuretics or to other sulfonamide-derived drugs.

Warnings: Excessive potassium intake may cause hyperkalemia. Potassium supplements should not be given with Aldactazide. Do not administer concurrently with other potassium-sparing diuretics. Sulfonamide derivatives including thiazides have been reported to exacerbate or activate systemic lupus erythematosus. Spironolactone has been shown to be a tumorigen in chronic toxicity studies in rats. In one study using 25, 75 and 250 times the usual daily human dose (2 mg/kg) there was a statistically significant dose-related increase in benign adenomas of the thyroid and testes. In female rats there was a statistically significant increase in malignant mammary tumors at the mid-dose only. In male rats there was a dose-related increase in proliferative changes in the liver. At the highest dosage level (500 mg/kg) the range of effects included hepatocytomegaly, hyperplastic nodules and hepatocellular carcinoma; the last was not statistically significant.

Precautions: Patients should be carefully evaluated for possible disturbances of fluid and electrolyte balance. Hyperkalemia may occur in patients with impaired renal function or excessive potassium intake and can cause cardiac irregularities which may be fatal. Hypokalemia may develop as a result of profound diuresis, particularly when Aldactazide is used concomitantly with loop diuretics, glucocorticoids or ACTH. Transient elevation of BUN may occur. Reversible hyperchloremic metabolic acidosis may occur in some patients with decompensated hepatic cirrhosis. Dilutional hyponatremia or rarely low-salt syndrome may develop. Gynecomastia may develop and in rare instances some breast enlargement may persist. Thiazides may alter the metabolism of uric acid and carbohydrates with possible hyperuricemia, gout and decreased glucose tolerance. Vascular responsiveness to norepinephrine is reduced. Thiazides may also increase the responsiveness to tubocurarine. The antihypertensive effects of hydrochlorothiazide may be enhanced in sympathectomized patients. Thiazides may decrease serum PBI levels and prolonged therapy may induce hypercalcemia and hypophosphatemia. Spironolactone may and hydrochlorothiazide does cross the placental barrier. Use in pregnant women requires that the anticipated benefit be weighed against possible hazards to the fetus. Breast feeding should be discontinued when Aldactazide is being used.

Adverse Reactions: *Associated with spironolactone*: Gynecomastia is observed not infrequently. Gastrointestinal symptoms including cramping and diarrhea, drowsiness, lethargy, headache, maculopapular or erythematous cutaneous eruptions, urticaria, mental confusion, drug fever, ataxia, inability to achieve or maintain erection, irregular menses or amenorrhea, postmenopausal bleeding, hirsutism and deepening of the voice. Carcinoma of the breast has been reported but a cause-and-effect relationship has not been established. *Associated with thiazides*: Gastrointestinal symptoms (anorexia, nausea, vomiting, diarrhea, abdominal cramps), purpura, thrombocytopenia, leukopenia, agranulocytosis, dermatologic symptoms (cutaneous eruptions, pruritus, erythema multiforme), paresthesia, acute pancreatitis, jaundice, dizziness, vertigo, headache, xanthopsia, photosensitivity, necrotizing angiitis, aplastic anemia, orthostatic hypotension, muscle spasm, weakness and restlessness. Adverse reactions are usually reversible upon discontinuation of Aldactazide.

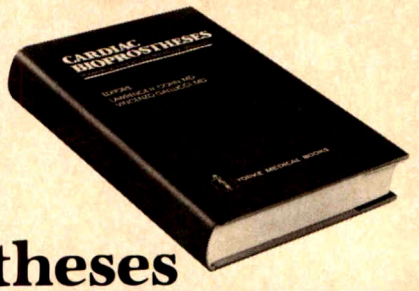
The most up-to-date presentation of the latest data on the entire range of clinical, bioengineering, pathology, and long-range follow-up issues on cardiac tissue valves.



Cardiac Bioprostheses

Proceedings of the Second International Symposium Rome, Italy, May 17-19, 1982

edited by Lawrence H. Cohn, MD, and Vincenzo Gallucci, MD
ISBN 0-914316-34-6, 609 pp., illus., Nov. 1982., $65.00

An international program committee organized this symposium on a strictly competitive abstract basis. It was held less than six months ago. One-hundred-eighty abstracts were submitted and 45 in 8 categories were accepted. Virtually every major cardiovascular center in the world that has any meaningful experience with cardiac bioprosthetic valves was represented. Nowhere will you find between two covers as much *current* information on the field of cardiac valves.

Almost 20 years have gone by since the first reports of homograft valve replacement by Drs. Donald Ross and Brian Barratt-Boyes and almost 10 years since the first reports began to appear about commercially available, quality-controlled porcine bioprosthetic and bovine pericardial valves. This book brings you completely up-to-date on what has happened since and what is happening *today*.

If your interests include the clinical, pathological and bioengineering aspects of cardiac bioprostheses then this book is a *must buy!* It should not be missing from your own professional library.

Who are the editors?

Lawrence H. Cohn, MD, is Professor of Surgery, Harvard Medical School, and Cardiothoracic Surgeon, Brigham and Womens' Hospital. He is the author of *Modern Techniques in Surgery* and co-author of the new annual, *Cardiology*, now available in its second issue, *Cardiology 1982.*

Vincenzo Gallucci, MD, is Professor of Cardiovascular Surgery, Departments of Cardiovascular Surgery and Cardiology, University of Padova Medical School, Padova, Italy.

The end of the "one-defibrillator-meets-all-needs" theory.

From the field to the various departments in the hospital, cardiac care offers more problems and situations than one system can efficiently handle.

Which is why Physio-Control has a family of LIFEPAK® defibrillator/monitors. Each one gives you specialized features designed to meet your specific needs.

You can depend on the whole LIFEPAK family for ease of operation and outstanding reliability. And service from the best in the industry. Physio-Control.

You can't beat the system.

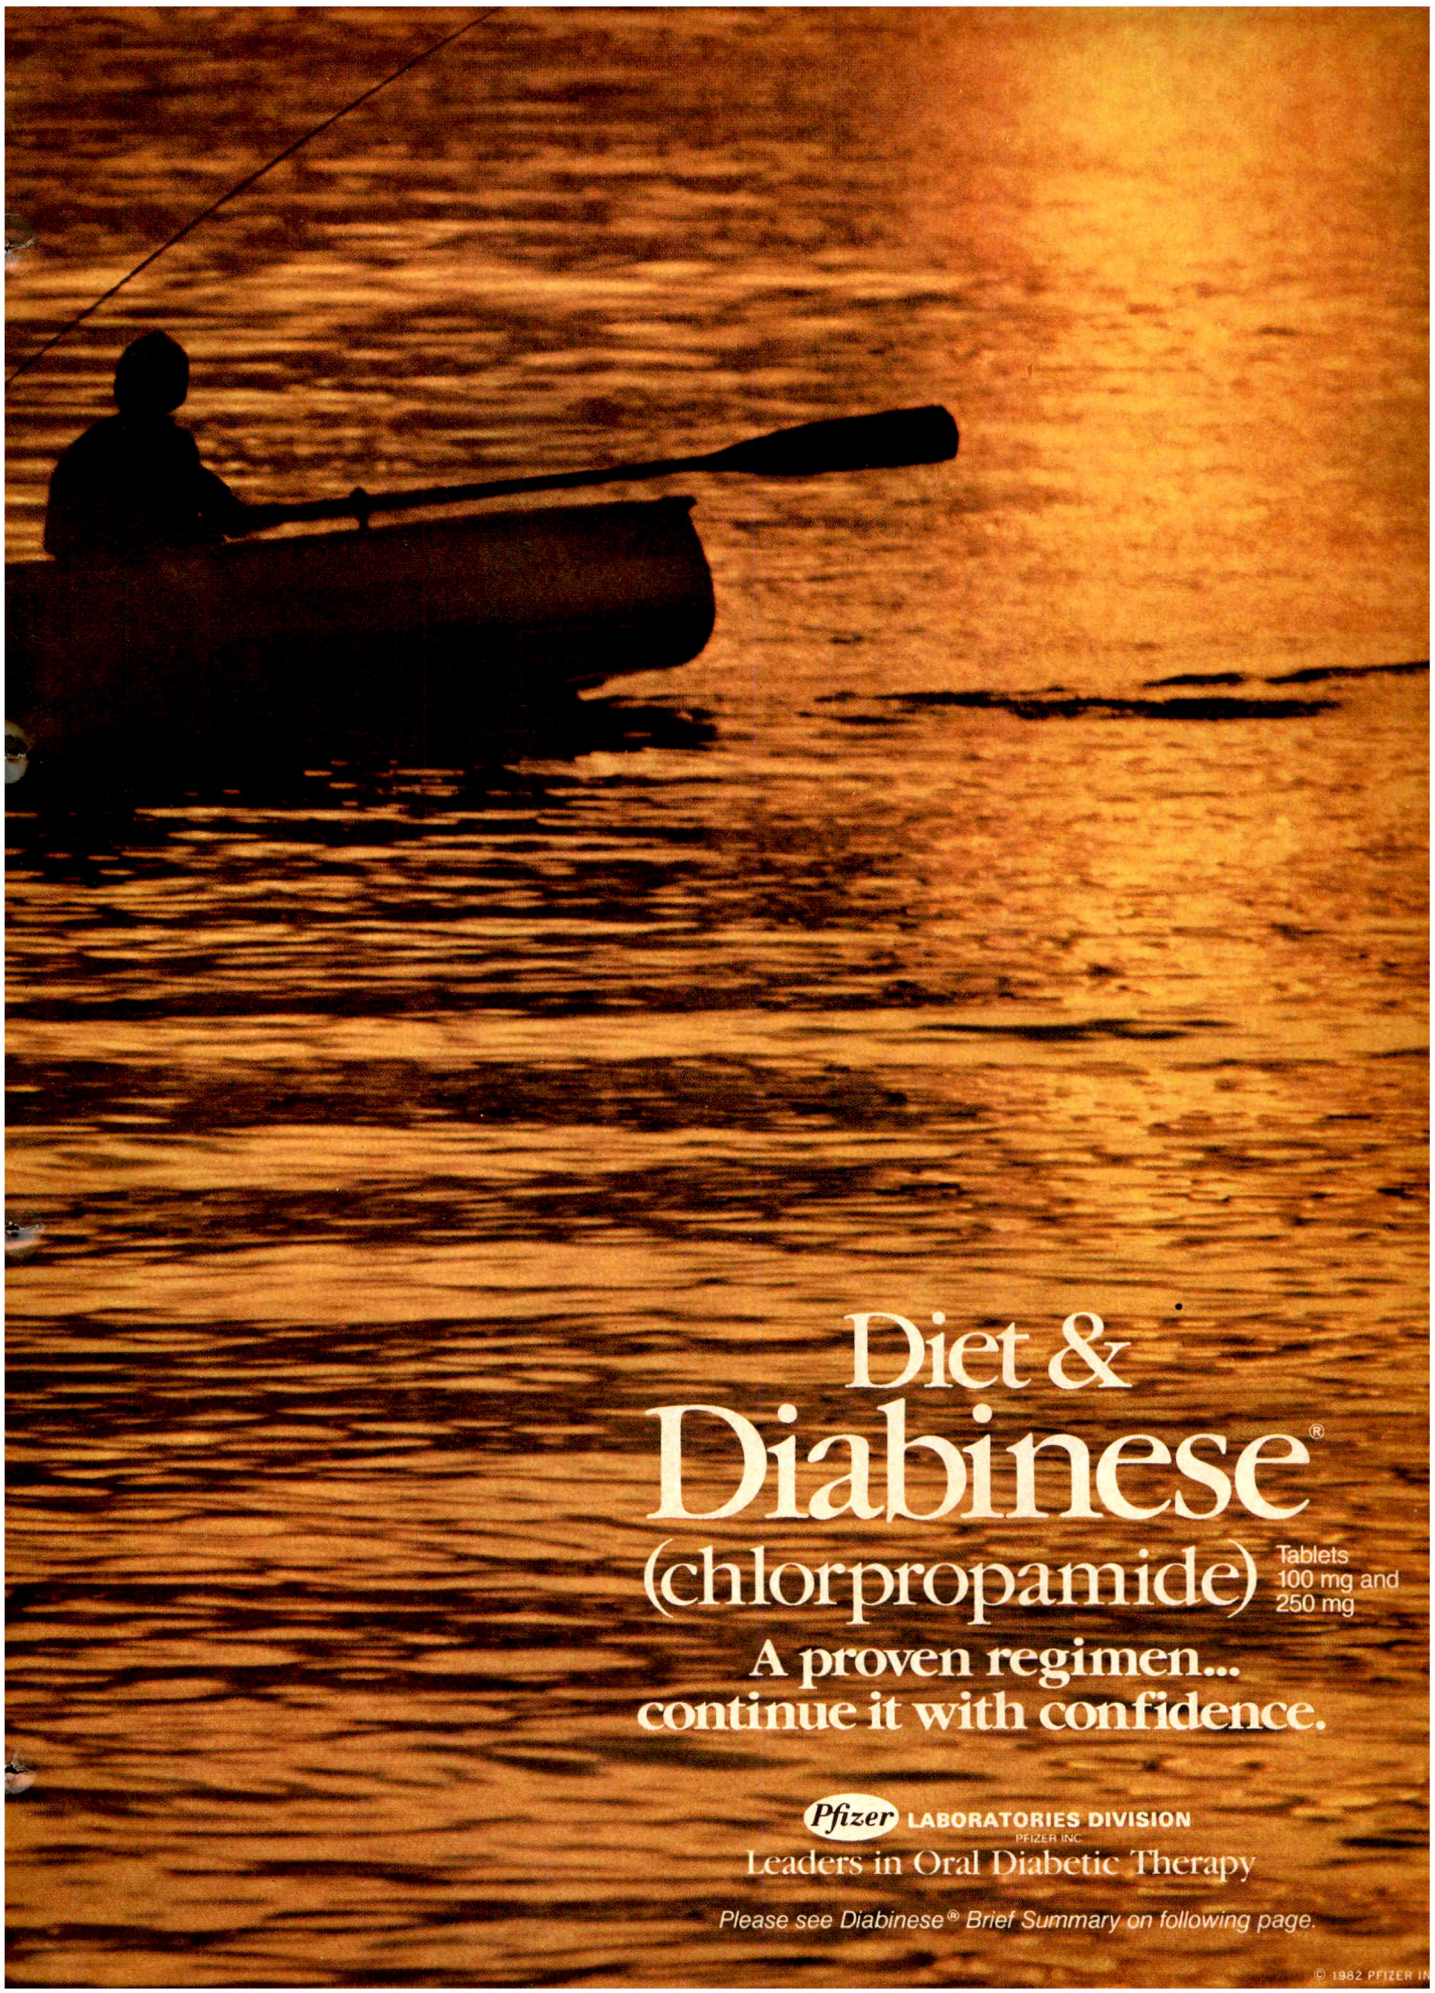
The Secure Diabetic
When diet alone has failed in NIDDM, successful management with diet and Diabinese® (chlorpropamide) is a source of great security to both patient and physician.
By safely lowering blood sugar, once-a-day Diabinese provides uncomplicated control every day for nearly a million secure diabetics.*
Diabinese is the most widely prescribed oral anti-diabetic agent. Its extensive record of efficacy and safety gives physicians confidence that their patients will be well controlled...while the once-daily regimen, regardless of dosage, helps assure compliance. And, Diabinese is economical.
*As with all sulfonylureas, hypoglycemia may occur with Diabinese, especially when dosage is not properly adjusted to the patient's requirements.



Diet &
Diabinese®
(chlorpropamide)
Tablets
100 mg and
250 mg
A proven regimen...

Diet & Diabinese (chlorpropamide)

Tablets 100 mg and 250 mg

A proven regimen... continue it with confidence.

BRIEF SUMMARY
DIABINESE® (chlorpropamide) Tablets

Contraindications: Diabinese is not indicated in patients having juvenile or growth-onset diabetes mellitus, severe or unstable "brittle" diabetes, and diabetes complicated by ketosis and acidosis, diabetic coma, major surgery, severe infection, or severe trauma. Diabinese is contraindicated during pregnancy. Serious consideration should be given to the potential hazard of its use in women of childbearing age who may become pregnant.
Diabinese is contraindicated in patients with serious impairment of hepatic, renal, or thyroid function.
Precautions: Use chlorpropamide with caution with barbiturates, in patients with Addison's disease or in those ingesting: alcohol, antibacterial sulfonamides, thiazides, phenylbutazone, salicylates, probenecid, dicoumarol or MAO inhibitors. Adequate dietary intake should be assured in all patients using Diabinese.
Warnings: DIABINESE (CHLORPROPAMIDE) SHOULD NOT BE USED IN JUVENILE DIABETES OR IN DIABETES COMPLICATED BY ACIDOSIS, COMA, SEVERE INFECTION, MAJOR SURGICAL PROCEDURES, SEVERE TRAUMA, SEVERE DIARRHEA, NAUSEA AND VOMITING, ETC. HERE, INSULIN IS INDISPENSABLE.
HYPOGLYCEMIA, IF IT OCCURS, MAY BE PROLONGED. (SEE ADVERSE REACTIONS.) IN INSTANCES OF CONCOMITANT USE WITH INSULIN, PATIENTS SHOULD BE CAREFULLY MONITORED.
Adverse Reactions: Usually dose-related and generally respond to reduction or withdrawal of therapy. Generally transient and not of a serious nature and include anorexia, nausea, vomiting and gastrointestinal intolerance; weakness and paresthesias.
Certain untoward reactions associated with idiosyncrasy or hypersensitivity have occasionally occurred, including jaundice, skin eruptions rarely progressing to erythema multiforme and exfoliative dermatitis, and probably depression of formed elements of the blood. They occur characteristically during the first six weeks of therapy. With a few exceptions, these manifestations have been mild and readily reversible on the withdrawal of the drug. The more severe manifestations may require other therapeutic measures, including corticosteroid therapy. Diabinese should be discontinued promptly when the development of sensitivity is suspected.
Jaundice has been reported, and is usually promptly reversible on discontinuance of therapy. THE OCCURRENCE OF PROGRESSIVE ALKALINE PHOSPHATASE ELEVATION SHOULD SUGGEST THE POSSIBILITY OF INCIPIENT JAUNDICE AND CONSTITUTES AN INDICATION FOR WITHDRAWAL OF THE DRUG.
Leukopenia, thrombocytopenia and mild anemia, which occur occasionally, are generally benign and revert to normal, following cessation of the drug.
Cases of aplastic anemia and agranulocytosis, generally similar to blood dyscrasias associated with other sulfonylureas, have been reported.
BECAUSE OF THE PROLONGED HYPOGLYCEMIC ACTION OF DIABINESE, PATIENTS WHO BECOME HYPOGLYCEMIC DURING THERAPY WITH THIS DRUG REQUIRE CLOSE SUPERVISION FOR A MINIMUM PERIOD OF 3 TO 5 DAYS, during which time frequent feedings or glucose administration are essential. The anorectic patient or the profoundly hypoglycemic patient should be hospitalized.
Rare cases of phototoxic reactions have been reported.
Edema associated with hyponatremia has been infrequently reported. It is usually readily reversible when medication is discontinued.
Dosage: The total daily dosage is generally taken at a single time each morning with breakfast. Occasionally, cases of gastrointestinal intolerance may be relieved by dividing the daily dosage. A LOADING OR PRIMING DOSE IS NOT NECESSARY AND SHOULD NOT BE USED. The mild to moderately severe, middle-aged, stable diabetic should be started on 250 mg daily. Because the geriatric diabetic patient appears to be more sensitive to the hypoglycemic effect of sulfonylurea drugs, older patients should be started on smaller amounts of Diabinese, in the range of 100 to 125 mg daily.
After five to seven days following initiation of therapy, dosage may be adjusted upward or downward in increments of 50 to 125 mg at intervals of three to five days. PATIENTS WHO DO NOT RESPOND COMPLETELY TO 500 MG DAILY WILL USUALLY NOT RESPOND TO HIGHER DOSES. Maintenance doses above 750 mg daily should be avoided.
Supply: 100 mg and 250 mg, blue, 'D'-shaped, scored tablets.
More detailed professional information available on request.

Congestive Heart Failure

Mechanisms, Evaluation and Treatment
Dean T. Mason, M.D.

This rare treatment of such a multifaceted subject provides an unusual opportunity for the busy clinician to add to his knowledge in a minimum amount of time. Any area of immediate interest can be rapidly located and as much data as needed can be quickly extracted. The concentration on improved clinical management will be appreciated by every internist, cardiologist, generalist, and any professional involved in cardiovascular medicine.

Dean Mason, President of the American College of Cardiology, has organized this monograph within the three areas relevant to an understanding of congestive heart failure: *mechanisms, evaluation* and *treatment*. Fifty-six recognized authorities have been assembled by Dr. Mason, each contributing their expertise to make this book the foremost text covering the highly important and common disorders of abnormal heart function.

This presentation of recent advances in basic research and clinical progress has been highly acclaimed for its major contribution to the improvement of patient care. We invite you to see if you don't agree. Order and take 30 days to look over the book. If you're not totally satisfied, return it.

About the author . . . Dean T. Mason, M.D.

Professor of Medicine, Professor Physiology, Chief of Cardiovascular Medicine, University of California, School of Medicine, Davis.

President, American College of Cardiology; President, Western Society for Clinical Research.

Member of the American Board of Internal Medicine Cardiovascular Diseases.

Has authored more than 400 original articles on cardiovascular science and clinical cardiology.

Serves on the editorial boards of The American Journal of Cardiology, The Journal of Clinical Investigation, Circulation, Chest, Clinical Pharmacology and Therapeutics, Catheterization and Cardiovascular Diagnosis, and Heart and Lung.

Recipient of Experimental Therapeutics Award in 1973 from the American Society of Pharmacology and Experimental Therapeutics, the Research Awards in 1965 from the American Therapeutic Society, and the Theodore and Susan B. Cummings Humanitarian Awards in 1972, 1973, and 1975 from the U.S. State Department and the American College of Cardiology.

YORKE MEDICAL BOOKS Box C-757, Brooklyn, N.Y. 11205

Please send me a copy of CONGESTIVE HEART FAILURE for 30 days free examination and use. If I decide to keep it, your invoice will be honored (**$45.00** plus shipping cost). Otherwise, the book will be returned for full credit or refund.

☐ Full payment enclosed, publisher absorbs shipping cost.
☐ Send invoice (U.S. and Canada only)
Countries outside Western Hemisphere: add $5.00 per copy.

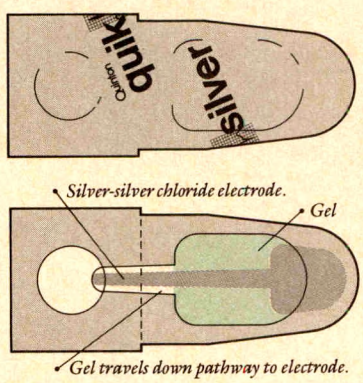
A NEW STANDARD FOR RESTING ELECTRODES.

It used to be a tough choice. You could endure the time-consuming mess of reusable electrodes. Or pay the considerable expense of disposable electrodes.

You don't have to make that choice anymore. Because now there's a new standard for resting electrodes: Quik-Silver™ by Quinton.

A new standard for performance.

The first thing you'll notice about a Quik-Silver electrode is that it doesn't look like an ordinary electrode. That's because it was engineered to be superior.



Quinton started with silver. As the leader in stress test electrodes, we knew the silver-silver chloride electrode offered unparalleled performance. We made a commitment not to sacrifice that performance. The result: Quik-Silver is the first resting electrode ever to offer the benefits of silver-silver chloride. The first to offer superior electrical characteristics. And one of the few to offer defibrillation recovery.

A new standard for convenience.

Quik-Silver makes ECG testing as simple as one, two, three. Its low-profile design incorporates a gel receptacle at one end of the strip and a silver-silver chloride electrode at the other end. To apply, simply insert the electrode into the clip, stick it on the patient and press down on the tab in the center of the clip. When you see gel come out the vent hole, you're ready to test. No mess. No hassle. And like the name says, it's fast.

Compare it to traditional reusable electrodes, a Welsh cup, for instance. The Welsh cup is time-consuming, messy and unsanitary. Quik-Silver is sanitary and can be applied in a fraction of the time. And unlike Welsh cups, it is designed to stick to the patient—and stay put.

A new standard for cost-effectiveness.

Superior performance. Unmatched convenience. You'd expect Quik-Silver to be more expensive. Just the opposite. Because of Quinton's state-of-the-art design, Quik-Silver can be produced far more efficiently than standard electrodes. So we can offer it to you for considerably less.

Even the clip is cost efficient. It's designed to adapt to your existing patient cables.

There's a new standard of excellence in resting electrodes. For more information on Quik-Silver, call Quinton at 1-800-426-0347. Or write us at 2121 Terry Avenue, Seattle, WA 98121. Telex 328840. Distributed worldwide.

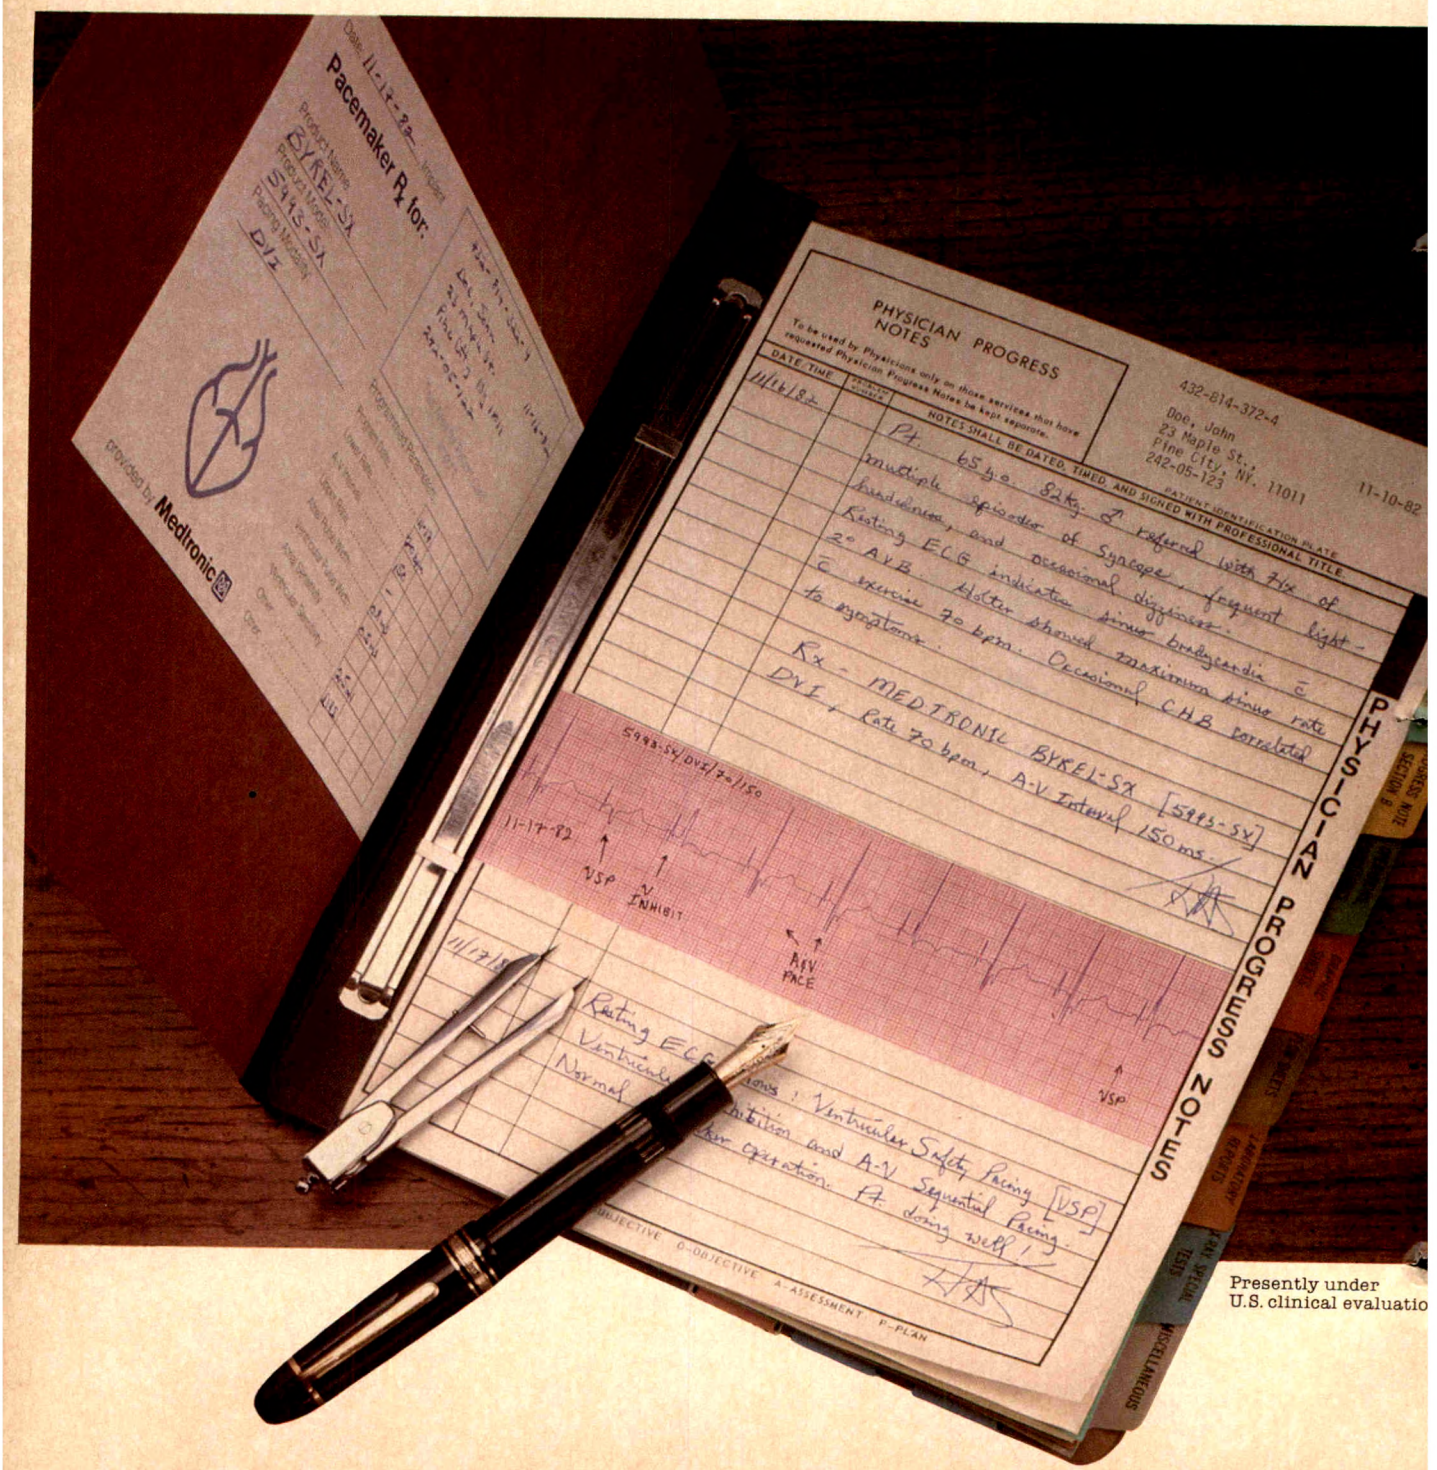
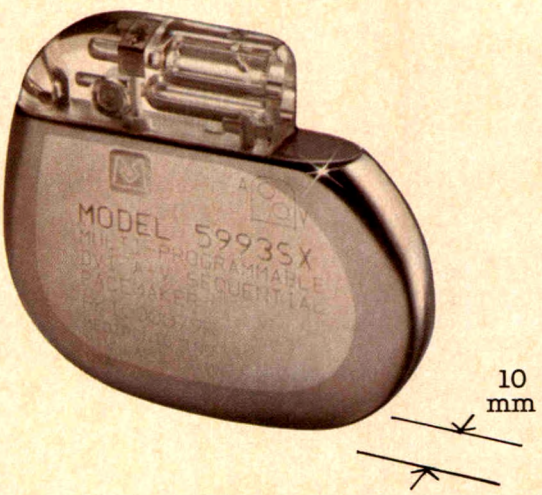
New Byrel-SX.™ Small, smart



Presently under
U.S. clinical evaluatio

and friendly.



State of the Heart A-V Sequential Pacing.

Introducing the most flexible A-V Sequential Pacemaker.

Small.

Physiologically sized and shaped for maximum patient comfort. Byrel-SX™ weighs just 52 grams.

Smart.

The most programmable A-V sequential pacemaker. Byrel-SX™ is a non-committed system, and features Ventricular Safety Pacing to provide:

- Programmable A-V Intervals
- Ventricular inhibition

Friendly.

Byrel™ brand pacemakers have long been known for their dependability, reliability, ease of programming, and ease of follow-up.

These are Medtronic differences physicians recognize and need.

The new Byrel-SX™, leading the way in A-V Sequential pacing. For further information call toll free 1-800-328-2518.

Medtronic

Power Source Depletion Characteristics

Initial Stage

Mode	as programmed
Voltage	2.2 V
Magnet rate	75 bpm

Secondary Stage

Mode	VVI at 65 bpm
Voltage	2.0 V

INTENDED USE

The Model 5993-SX universal A-V pulse generator has a wide range of application in patients requiring permanent cardiac pacing or to protect against arrhythmias related to the sequence of cardiac impulse propagation.

In the A-V sequential (DVI) mode, the Model 5993-SX has application in the following:

Sick Sinus Syndrome (sinus brady-cardia, sinus arrest, S-A block, and the brady-tachy syndrome).

A-V nodal reentrant tachycardias. (Short A-V interval settings may be useful in controlling reentrant tachy-cardias.)

Atrial and ventricular ectopic arrhythmias.

At any time, the Model 5993-SX can be programmed to the VVI mode in which case the device functions as a ventricular inhibited pulse generator. This mode is intended primarily as a backup mode in situations where it is necessary to disable the atrial circuitry (e.g., atrial lead malfunction).

NOTE: The Medtronic® Model 5993-SX A-V pulse generator is under clinical investigation. The procedures for using this pulse generator, as well as its safety and efficacy, will be evaluated during this investigational study according to the Clinical Investigation Protocol. Therefore, the "Intended Use" section is based on Medtronic's experience with other physiologic pulse generators. No claims for safety and efficacy can be made for the Model 5993-SX pulse generator during its clinical investigation. Patients should be advised that the Model 5993-SX generator is under clinical investigation.

CONTRAINDICATIONS

There are no known contraindications to the use of pacing as a therapeutic modality for control of heart rate. The patient's age and medical condition, however, may dictate the particular pacing system, mode of operation, and implantation procedure used by the physician. In the DVI mode, atrial pacing is ineffective in the presence of chronic atrial fibrillation of flutter.

WARNINGS

Diathermy should not be used on patients with pacemakers because of possible heating effects in the pulse generator and at the implant site. Electrosurgical units should never be used in the vicinity of unipolar pulse generators because of danger of introducing fibrillatory currents into the heart via the implanted pulse generator/lead. Pulse generators may be damaged by defibrillatory discharges if the paddles are placed over the implanted pulse generator.

Positioning a magnet or the programmer over the pulse generator makes it subject to programming. Do not use electrocautery, diathermy, or any other source of electromagnetic interference in the vicinity of the patient once a magnet or programmer has been positioned over the pulse generator.

PRECAUTIONS

The physician should be aware that all pulse generators will ultimately cease to function due to cell depletion, and may fail at any time due to random component or battery failures which cannot be predicted prior to failure. Also that the pacing system may cease to function at any time due to lead-related problems such as displacement, fracture, fibrotic tissue formation, elevated thresholds and medical complications, and that proper operation may be affected by electrical interference from certain electrical equipment.

SIDE EFFECTS

Body rejection phenomena, including local tissue reaction, muscle and nerve stimulation, infection, erosion of pulse generator/lead through skin, transvenous lead-related thrombosis, embolism and cardiac tamponade.

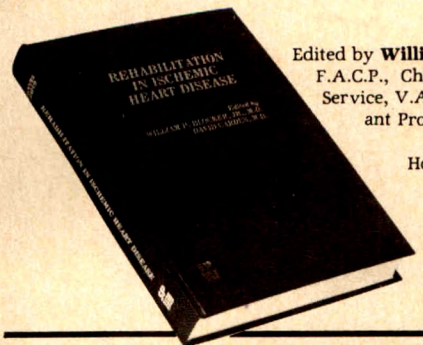
This book contains the most complete list of cardiac risk factors to be found in any text. . .



Edited by **William P. Blocker, Jr., M.D.,** F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine, Baylor College of Medicine, Houston, and **David Cardus**, M.D., F.A.C.C., Professor of Physiology and Rehabilitation, Baylor College of Medicine, Houston, Texas.

REHABILITATION IN ISCHEMIC HEART DISEASE

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

Approx. 500 pp., 188 figs. & tbls., large format 8½x11, 1982, $80.00

NITROSTAT®
(nitroglycerin tablets, USP)

Before prescribing, please see full prescribing information. A Brief Summary follows:

INDICATIONS
Nitroglycerin is indicated for the prophylaxis, treatment and management of patients with angina pectoris.

CONTRAINDICATIONS
Sublingual nitroglycerin therapy is contraindicated in patients with early myocardial infarction, severe anemia, increased intracranial pressure, and those with a known hypersensitivity to nitroglycerin.

PRECAUTIONS
Only the smallest dose required for effective relief of the acute anginal attack should be used. Excessive use may lead to the development of tolerance. Nitrostat tablets are intended for sublingual or buccal administration and should not be swallowed. The drug should be discontinued if blurring of vision or drying of the mouth occurs. Excessive dosage of nitroglycerin may produce severe headaches.

ADVERSE REACTIONS
Transient headache may occur immediately after use. Vertigo, weakness, palpitation, and other manifestations of postural hypotension may develop occasionally, particularly in erect, immobile patients. Syncope due to nitrate vasodilation has been reported. Alcohol may accentuate the cerebral ischemia symptoms.

METHOD OF ADMINISTRATION
One tablet should be dissolved under the tongue or in the buccal pouch at the first sign of an acute anginal attack. The dose may be repeated approximately every five minutes until relief is obtained. Nitrostat may be used prophylactically five to ten minutes prior to engaging in activities which might precipitate an acute attack.

HOW SUPPLIED
Nitrostat is supplied in four strengths in bottles containing 100 tablets each, with color-coded labels, and in color-coded Patient Convenience Packages of four bottles of 25 tablets each.

0.15 mg (1/400 grain):
N 0071-0568-24—Bottle of 100 tablets;
N 0071-0568-13—Convenience Package.

0.3 mg (1/200 grain):
N 0071-0569-24—Bottle of 100 tablets;
N 0071-0569-13—Convenience Package.

0.4 mg (1/150 grain):
N 0071-0570-24—Bottle of 100 tablets;
N 0071-0570-13—Convenience Package.

0.6 mg (1/100 grain):
N 0071-0571-24—Bottle of 100 tablets;
N 0071-0571-13—Convenience Package.

NATURE
HAS A WAY
OF PROTECTING
ITS OWN.

So does NITROSTAT®
(nitroglycerin tablets, USP)

Just by the way it's made, NITROSTAT, too, has built-in protection—protection against loss of nitroglycerin. In fact, NITROSTAT is more stable than conventional nitroglycerin tablets under all conditions of temperature and humidity tested.

But that's not all. Average assay still shows better than 100% of label claim for at least 60 months after manufacture of NITROSTAT. Because of this stability NITROSTAT has a five-year expiration date.*

What's more, only NITROSTAT Tablets are available in convenient packages of 4 x 25 tablets. So emergency angina relief can be ready when needed in four different locations. "Because of its rapid action, long-established efficacy, and low cost, nitroglycerin is the most useful drug among the organic nitrates that can be given sublingually."[1] NITROSTAT... useful alone or as concomitant therapy with long-acting nitrates or propranolol.

*Five-year expiration date when stored at recommended storage conditions in an unopened bottle. Data on file, Medical Affairs Dept. Parke-Davis.

Relation Between Functional Response to Nitroglycerin and Extent of Myocardial Necrosis in Dogs: Mapping of the Left Ventricle by 2-Dimensional Echocardiography

KEICHO SHIMOURA, MD, SAMUEL MEERBAUM, PhD, TATSUO SAKAMAKI, MD, SHUJI KONDO, MD, MICHAEL C. FISHBEIN, MD, JACOB Y-RIT, MD, CHUWA TEI, MD, PRAVIN M. SHAH, MD, and ELIOT CORDAY, MD

The relation between functional response to brief nitroglycerin infusions and extent of myocardial damage was studied sequentially in closed-chest dogs with acute occlusion of the left anterior descending coronary artery. Two-dimensional echocardiography was used to derive segmental left ventricular (LV) function (systolic fractional area change and systolic wall thickening), and this function was compared with the extent of necrosis measured 5 hours after occlusion in equivalent segments of corresponding pathologic slabs. Two-dimensional echocardiographic study before the dogs were killed indicated that remote nonnecrotic segments always responded to nitroglycerin by significant augmentation of segmental LV function. Segments in which necrosis was <40% showed a significant nitroglycerin-induced potentiation in segmental LV function. In contrast, segments in which necrosis was >60% had no potentiation with nitroglycerin. In those segments in which eventual necrosis was 60 to 80%, significant nitroglycerin-induced augmentation in segmental LV function was observed only before and 30 minutes after the coronary occlusion. When the degree of necrosis was >80%, no significant potentiation of segmental LV function was observed even as early as 30 minutes after occlusion. Thus, the degree of nitroglycerin-induced potentiation of segmental cardiac function is closely associated with the extent of myocardial necrosis in the particular ventricular segment. Two-dimensional echocardiography coupled with a nitroglycerin potentiation test might be useful for assessment of the viability of ischemic myocardium.

Nitroglycerin administration is known to be associated with systemic effects on both afterload and preload, and also alters the distribution of myocardial blood flow.[1–10] In addition to its application for treatment, nitroglycerin has frequently been used in patients with ischemic heart disease to elicit a response that might characterize functional viability, such as improvement of abnormal wall motion in asynergic ischemic segments.[11–18] Nitroglycerin-induced reversal of regional wall motion abnormalities generally correlated well with and was often predictive of salvage of corresponding regions after subsequent bypass revascularization surgery.[15] However, few systematic data have been reported on the relation between the underlying pathologic characteristics of ischemic asynergic left ventricular (LV) regions[19,20] and their response during brief nitroglycerin interventions.

In this study, we examined and correlated in closed-chest dogs the extent of myocardial necrosis in LV segments in relation to their functional response to nitroglycerin as defined by 2-dimensional (2-D) echocardiography. We also studied the time course of the segmental functional response to brief nitroglycerin interventions during coronary artery occlusions, and related the progressive changes in response to eventual myocardial segment histopathology.

From the Division of Cardiology, Department of Medicine, Cedars-Sinai Medical Center, University of California Los Angeles School of Medicine, Los Angeles, California. This study was supported in part by Grants HL 14644-09 and HL 17651-08 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland; the Ahmanson Foundation, the W. M. Keck Foundation, the Mitchell Family Foundation; Mr. and Mrs. Beryl Adams, Ms. Joan and Mrs. Pearl Borinstein, Mr. and Mrs. Ira Gershwin, Mr. and Mrs. E. E. Fogelson, Mrs. Suzanne Cummings, Mr. and Mrs. Nicolai Joffe, Mr. and Mrs. Hal Wallis, Mrs. Dorothy Forman, and Mr. and Mrs. Randolph Scott, Los Angeles, California. Manuscript received January 5, 1983; revised manuscript received March 14, 1983, accepted March 15, 1983.

Methods

Experimental procedures: Ten mongrel dogs, weighing 21 to 36 kg, were anesthetized intramuscularly with morphine (2 mg/kg) and intravenously with sodium pentobarbital (30 mg/kg). The dogs were respirated with a Harvard ventilator through a cuffed endotracheal tube. Echocardiographic studies and all catheter placements were performed in the closed-chest preparation. A 7Fr catheter was placed into the ascending aorta and a 7Fr pigtail catheter into the left ventricle. Aortic and LV blood pressures were recorded using Statham P23Db transducers. LV dP/dt was derived by means of resistance-capacitance differentiation. A 7Fr Swan-Ganz thermodilution balloon-tipped catheter was inserted into the pulmonary artery and connected to an Edwards cardiac output computer 9520 for cardiac output measurements. Pressures, LV dP/dt (first differential of LV pressure), and a precordial electrocardiogram were monitored simultaneously on an Electronics for Medicine recorder at a paper speed of 25 or 50 mm/s.

The left anterior descending coronary artery (LAD) was occluded in the closed-chest dogs with a 2 or 3Fr intracoronary balloon catheter at a site just beyond the first diagonal branch. Before coronary occlusion and 30, 60, 120, 180, and 300 minutes after LAD occlusion, a set of control (prenitroglycerin) measurements were obtained, including 2-D echocardiography, cardiac output, blood pressures, and the electrocardiogram. After individual control measurements were recorded, a nitroglycerin test was performed by intravenously administering nitroglycerin through a femoral vein catheter using a Harvard infusion pump. The infusion of nitroglycerin was controlled in a manner to cause a decrease in mean aortic pressure of approximately 10% from the respective prenitroglycerin control state (average nitroglycerin dose 3 μg/kg/min, range 1 to 6). After the aortic pressure had reached a steady state at the desired level, nitroglycerin infusion was maintained for 5 minutes, during which time the aforementioned set of recordings was repeated. Nitroglycerin was then discontinued until the next nitroglycerin test. The total period of individual nitroglycerin tests, performed before and after coronary occlusion, did not exceed 10 minutes. After 5 hours of LAD occlusion and a final set of control as well as nitroglycerin measurements, the dogs were killed and pathologic studies were performed, including delineation of myocardial necrosis in ventricular slabs.

Two-dimensional echocardiographic examination: A mechanical ultrasonic sector scanner (ATL Mark III, Advanced Technology Laboratories, Bellevue, Washington) was used to perform the 2-D echocardiographic studies. Echocardiographic examination of the heart was performed in closed-chest dogs according to methods previously detailed by our laboratory.[21–23]

Regional LV wall motion analysis of short-axis LV sections in individual beats was performed in a standardized manner. The geographic center of the epicardial outline and the junction between the anterior right ventricle and ventricular septum were used as internal reference points, defining an indexing line for standardized computer-aided (PDP 11/34 minicomputer) division of each cross section into eight 45° segments. In correcting for translation and rotation, a floating reference system of analysis was used in which the epicardial geographic centers and indexing lines of both end-diastolic and end-systolic outlines of individual beats were superimposed. Individual segmental systolic fractional area changes and systolic wall thickening were computed as indexes of myocardial contraction: percent systolic fractional area change (FAC%) = [(EDLA − ESLA)/EDLA] ×100; percent systolic wall thickening (WT%) = [(ESWT − EDWT)/EDWT] ×100, where EDLA = end-diastolic luminal area, ESLA = end-systolic luminal area, EDWT = end-diastolic wall thickness, ESWT = end-systolic wall thickness, and wall thickness = 2 × muscle area/(epicardial perimeter + endocardial perimeter).

Morphologic analysis: The dogs' hearts were excised and sectioned transversely into 5 slabs, each approximately 10 mm thick, parallel to the atrioventricular groove. Each slice was then incubated in triphenyltetrazolium chloride[24,25] and fixed in formalin for subsequent processing. The extent and the site of the necrosis were confirmed by histologic examination.[24,25] The triphenyltetrazolium-chloride–delineated areas of necrosis were compared with extent of asynergy and regional response to nitroglycerin, measured in 2-D echocardiographic LV sections corresponding to carefully matched equivalent anatomic slabs. This matching was performed using every structural landmark in both 2-D echocardiographic LV sections and anatomic slabs.

TABLE I, continued

	LVEDP (mm Hg)			CO (liters/min)			SV (ml/min)

5 hours	9.9 ±5.1	5.4 ±3.2†	−50.4 ±20.7	2.1 ±0.5	2.1 ±0.3	0.7 ±16.8	18.3 ±3.6	16.2 ±3.1	−9.3 ±20.5

CO = cardiac output; HR = heart rate; LV dP/dt = first differential of left ventricular pressure; LVEDP = left ventricular end-diastolic pressure; MAP = mean aortic pressure; SV = stroke volume.

Data analysis: Two-dimensional echocardiographic measurements in segments of LV short-axis sections were expressed as systolic fractional area change and systolic wall thickening, and were always derived for periods before and during nitroglycerin at the different times after LAD occlusion. The 2-D echocardiographically derived data on cardiac function were correlated with the extent of equivalent anatomic slab necrosis, also expressed as a percentage of each slab segment, measured with planimetry.[25]

Statistical analysis was performed by Student's paired *t* test. P values <0.05 were considered statistically significant.

Reproducibility: To study reproducibility, 2-D echocardiographic analysis was performed both by 1 observer at different times (intraobserver) and independently by 2 observers (interobserver) in 10 short-axis 2-D echocardiographic views, 1 view from each dog. Intra- and interobserver reproducibility study of segmental percent necrosis measurements was performed in 1 slab from each dog. A linear regression analysis was performed and a mean percent error was calculated.

Results

Effects of nitroglycerin on hemodynamic function: The nitroglycerin-induced hemodynamic changes at different stages of the LAD occlusion are summarized in Table I. Although aortic pressures appeared slightly increased after the LAD occlusion, this change was not statistically significant. Individual nitroglycerin injections decreased mean aortic pressure by 9 ± 3% (mean ± standard deviation, range 8 to 10%) from respective prenitroglycerin levels. Initially, spontaneous heart rate increased significantly soon after the LAD occlusion, but the rate did not change further throughout the 5-hour experimental period. Before the LAD occlusion, nitroglycerin caused a significant increase in heart rate (38 ± 21%). A significant but smaller increase in heart rate was also evident in response to nitroglycerin after the LAD occlusion (17 ± 14%, range 13 to 23%). Maximal LV dP/dt increased significantly and LV end-diastolic pressure decreased significantly during nitroglycerin testing, both before and throughout the LAD occlusion. Cardiac output, measured with thermodilution, increased significantly as a result of nitroglycerin before and 30 minutes after LAD occlusion. However, there was no significant nitroglycerin-induced change in cardiac output after 1, 2, 3, and 5 hours of the LAD occlusion. Calculated LV stroke volume decreased successively after the LAD occlusion, and was further reduced during the individual nitroglycerin test periods.

TABLE II Reproducibility of Duplicate Measurements of 2-D Echocardiographic Segmental LV Function, and Segmental Percent Necrosis in Pathologic Slabs

	r	Slope	Intercept (%)	SEE	Mean Error (%)
			Intraobserver Reproducibility		
FAC%	0.92	0.97	1.41	3.82	7.7 ± 7.0
WT%	0.93	0.90	1.80	7.06	23.5 ± 18.8
% Necrosis	0.98	0.94	0.69	2.82	2.7 ± 2.1
			Interobserver Reproducibility		
FAC%	0.90	0.90	5.26	3.90	9.4 ± 8.7
WT%	0.93	0.87	3.55	6.69	26.4 ± 20.3
% Necrosis	0.99	0.94	2.08	2.85	2.8 ± 2.9

FAC% = systolic fractional area change; r = correlation coefficient; SEE = standard error of the estimate; WT% = systolic wall thickening.

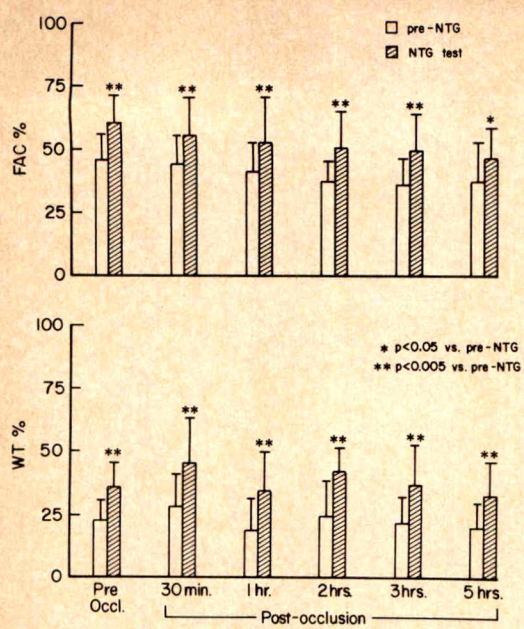

FIGURE 1. Alterations of 2-D echocardiographically derived segmental left ventricular function in a low papillary left ventricular cross section during nitroglycerin (NTG) tests performed before occlusion and up to 5 hours after left anterior descending artery occlusion (Occl.). Function was potentiated by nitroglycerin in all cardiac segments that were found to have no necrosis after 5 hours of left anterior descending artery occlusion. FAC % = systolic fractional area change; WT% = systolic wall thickening.

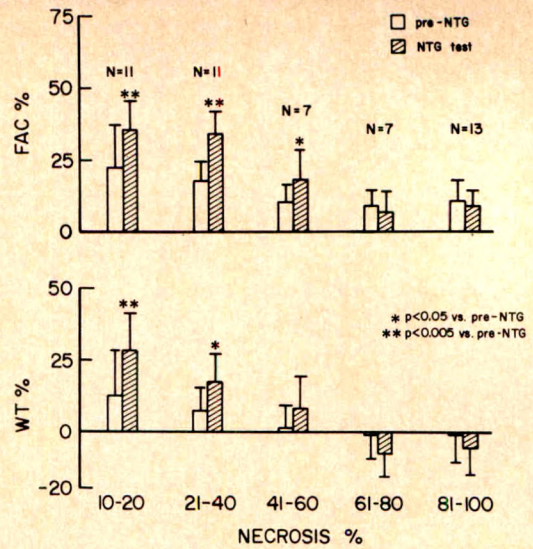

FIGURE 2. Relation between 2-D echocardiographically derived segmental functional response to nitroglycerin (NTG) just before death, and segmental extent of necrosis in equivalent left ventricular slabs 5 hours after left anterior descending artery occlusion. Necrotic involvement was delineated in slabs with triphenyltetrazolium chloride. FAC% = systolic fractional area change; WT% = systolic wall thickening.

Reproducibility: Data of linear regression analysis and mean percent errors are shown in Table II. Both intra- and interobserver reproducibility of segmental systolic fractional area change exhibited satisfactory correlation coefficients (r = 0.92, 0.90) and small mean percent errors (7.7, 9.4%), but mean percent errors of segmental systolic wall thickening were comparatively large (23.5, 26.4%), in spite of apparently adequate correlation coefficients (r = 0.93, 0.93). Reproducibility of segmental measurements of percent necrosis exhibited good correlation coefficients (r = 0.98, 0.99) and small mean percent errors (2.7, 2.8%).

Two-dimensional echocardiographic measurements: During nitroglycerin testing, LV ejection fraction, calculated from LV end-diastolic and end-systolic

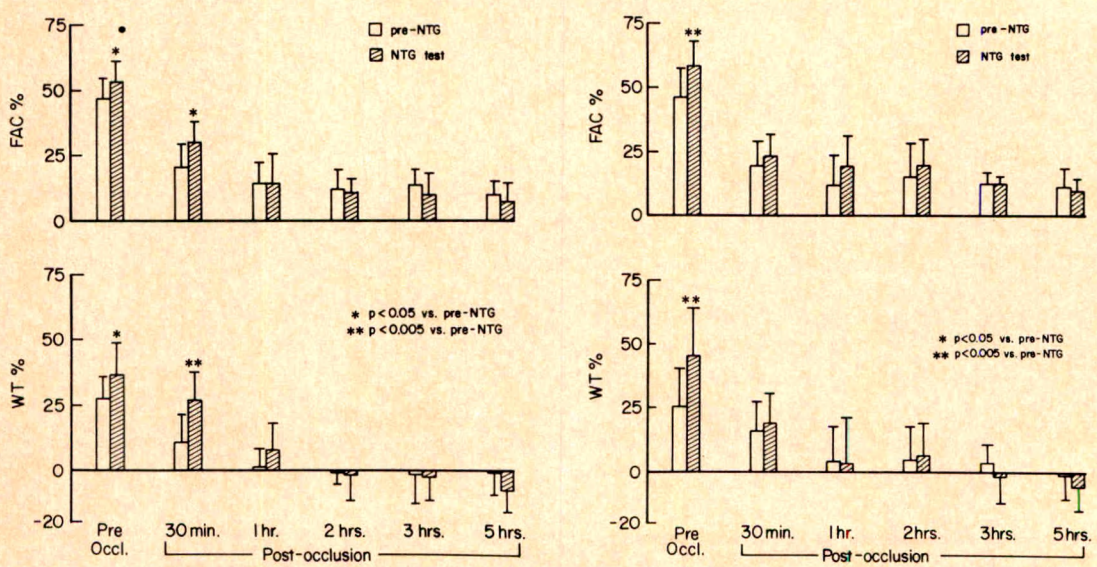

FIGURE 3. Left, time course of functional response to nitroglycerin of left ventricular segments in which the ultimate necrosis was between 61 and 80% after 5 hours of left anterior descending artery occlusion (Occl.). **Right,** time course of functional response to nitroglycerin of left ventricular segments in which the ultimate necrosis was >80% after 5 hours of left anterior descending artery occlusion. FAC% = systolic fractional area change; WT% = systolic wall thickening.

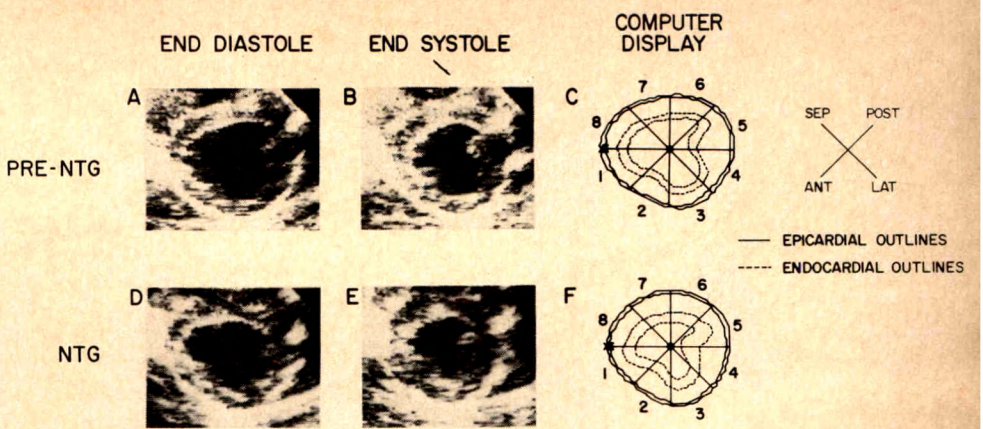

FIGURE 4. Two-dimensional echocardiographic images of left ventricular short-axis cross sections obtained at low papillary level before the left anterior descending artery occlusion. **A,** prenitroglycerin, end-diastolic image; **B,** prenitroglycerin, end-systolic image; **D,** end-diastolic image during nitroglycerin; **E,** end-systolic image during nitroglycerin; **C and F,** superimposed endocardial and epicardial outlines before and during nitroglycerin. volumes, increased significantly both before and throughout the LAD occlusion. After distal LAD occlusion, wall motion abnormalities observed with 2-D echocardiography were most distinct at the low papillary and near-apical LV levels. Hence, emphasis was placed on analyzing 2-D echocardiographic LV views in a short-axis low papillary level cross section.

Figure 1 shows 2-D echocardiographically derived data on segmental LV function (systolic fractional area change and systolic wall thickening) in remote nonischemic segments, whose site was corroborated by postmortem triphenyltetrazolium chloride staining of equivalent LV slabs. Significant augmentation of segmental LV function was observed in these remote segments during nitroglycerin testing at all times before and throughout the LAD occlusion.

Triphenyltetrazolium chloride staining of LV slabs after 5 hours of LAD occlusion indicated various extents of necrosis in different segments of the echo-delineated underperfused jeopardized LV zone. Figure 2 shows the relation between segmental extent of necrosis noted 5 hours after the LAD occlusion and 2-D echocardiographically derived segmental LV function measured just before death, both before and during the nitroglycerin test. In those segments in which the ultimate necrosis was <40%, a significant potentiation in segmental LV function was noted during nitroglycerin testing at 5 hours after the LAD occlusion. In segments where the

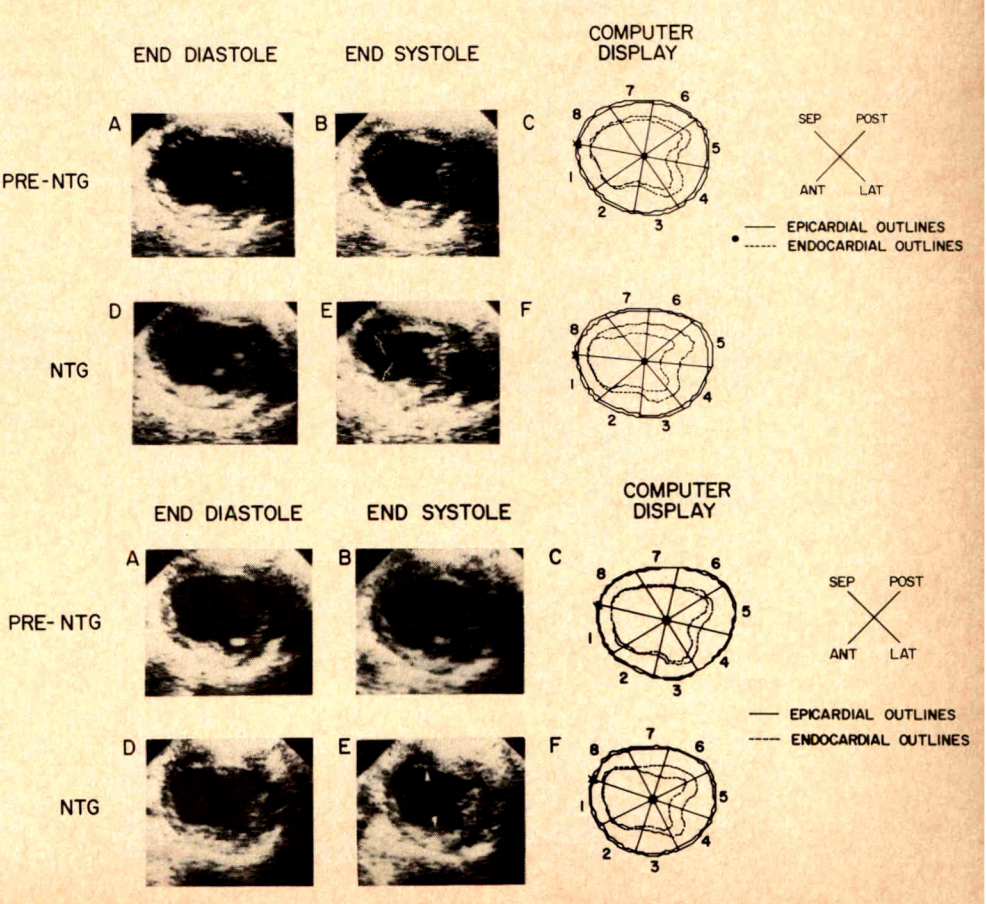

FIGURE 5. Two-dimensional echocardiographic images of left ventricular short-axis cross sections at a low papillary level, obtained 30 minutes (**top**) and 5 hours (**bottom**) after LAD coronary occlusion. **A,** prenitroglycerin, end-diastolic image; **B,** prenitroglycerin, end-systolic image; **D,** end-diastolic image during nitroglycerin test; **E,** end-systolic image during nitroglycerin test; **C and F,** superimposed endocardial and epicardial outlines before and during the brief nitroglycerin administration. The **arrows** separate the portion of the cardiac muscle that was potentiated by nitroglycerin from the characteristically thinned ischemic wall that failed to respond to nitroglycerin. Note that segment 1 did not respond to nitroglycerin as early as 30 minutes after LAD occlusion, as well as 5 hours after LAD occlusion. This segment proved to have >80% myocardial necrosis after the 5 hours of LAD occlusion (see also Figure 6). Segments 2 and 8 were potentiated by nitroglycerin 30 minutes after occlusion but not during subsequent nitroglycerin tests performed throughout the 5 hours of LAD occlusion. These segments exhibited 60 to 80% eventual necrosis. Segment 3 was potentiated both 30 minutes and 5 hours after LAD occlusion, and this segment proved to have myocardial necrosis <40%. Abbreviations as in Figure 4.

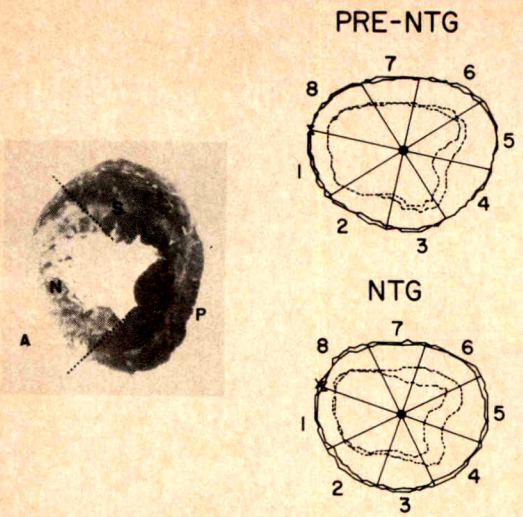

FIGURE 6. Triphenyl-tetrazolium-chloride stained left ventricular slab equivalent to low papillary 2-D echocardiographic cross section (from the same dog as in Figures 4 and 5), along with superimposed 2-D echocardiographic endocardial and epicardial outlines obtained before and during nitroglycerin (NTG) testing 5 hours after left anterior descending artery occlusion. Note that the size of the nitroglycerin nonresponsive region correlates well with the area of myocardial necrosis. A = anterior; N = myocardial necrosis area; P = posterior; S = interventicular septum.

extent of necrosis was 40 to 60%, nitroglycerin still caused significant potentiation in systolic fractional area change, but potentiation in systolic wall thickening was not significant. In those segments where the ultimate necrosis was found to be >60%, there was no potentiation with nitroglycerin in segmental LV function. In these segments further deterioration of segmental LV function was seen during nitroglycerin testing, but the decrease in function was not statistically significant.

The time course of the LV functional response to nitroglycerin in segments that exhibited ultimate necrosis >60%, is shown in Figure 3, both before and throughout the period of LAD occlusion. In segments where the ultimate extent of necrosis was 60 to 80%, significant nitroglycerin-induced augmentation in segmental LV function occurred before and at 30 minutes after LAD occlusion, but not at subsequent nitroglycerin test intervals during the 5-hour LAD occlusion (Figure 3, left). Thus, nitroglycerin failed to augment segmental LV function in these segments 1 hour after LAD occlusion. In segments where the ultimate necrosis was >80%, potentiation of segmental LV function in response to the nitroglycerin test was present before coronary artery occlusion, but there was no significant response of segmental LV function during the nitroglycerin test even as early as 30 minutes after the LAD occlusion (Figure 3, right).

Figures 4 and 5 show 2-D echocardiographic stop-frame images in end-diastole and end-systole, both before and during the nitroglycerin test, obtained before and 30 minutes as well as 5 hours after the LAD occlusion. Figure 6 shows a triphenyltetrazolium chloride–stained LV slab and compares it with the equivalent 2-D echocardiographically derived cross section studied 5 hours after LAD occlusion. These typical echocardiograms along with the superimposed computer-aided display illustrate the nitroglycerin potentiation in LV function before LAD occlusion and the absence of potentiation in segments that developed >60% necrosis 5 hours after LAD occlusion.

Discussion

It is clearly desirable and important to develop methods capable of differentiating potentially viable from irreversibly injured ischemic myocardium. Successful and accurate differentiation, preferably by reliable noninvasive diagnostic methods, may help anticipate and evaluate effects of appropriate treatments, such as bypass surgery or pharmacologic interventions.

In the current study, 2-D echocardiographic segmental analysis of LV short-axis cross sections after coronary occlusion revealed that remote nonischemic segments invariably exhibited significant nitroglycerin-induced functional augmentation. In the underperfused jeopardized zone, ischemic segments in which ultimate necrosis was <40% always exhibited significant nitroglycerin potentiation as late as 5 hours after occlusion. However, in segments in which necrosis was >60%, there was no potentiation of segmental LV function 5 hours after occlusion. We noted that significant nitroglycerin augmentation of segmental LV function was lost as early as 1 hour after LAD occlusion in segments with eventual 60 to 80% necrosis. In segments in which necrosis was >80%, there was no nitroglycerin potentiation even 30 minutes after occlusion.

Previous studies of nitroglycerin assessment of functional reserve: Nitroglycerin may improve cardiac contraction by reducing ventricular loading and altering the myocardial oxygen supply-to-demand ratio[11–16] and may also redistribute blood flow to ischemic zones.[1–10] Inotropic effects of nitroglycerin remain controversial.[1,6,12]

Previous clinical studies indicated that hypokinetic ventricular segments respond to nitroglycerin with improved wall motion, whereas areas of dyskinesia show almost no response.[11,13–15] Helfant et al[15] reported that a positive regional ventricular response to nitroglycerin appears to be predictive of corresponding regional benefits from coronary bypass surgery.[26] Banka et al[12] and Theroux et al[27] noted in experimental studies of acute coronary occlusion that nitroglycerin improved contraction of nonischemic and border zones, with reduction of potentiation toward the center of the ischemic zone. Bodenheimer et al,[19] in a clinical study, demonstrated that nitroglycerin-responsive LV areas were characterized by presence of histologically normal myocardium, whereas unresponsive areas were comprised of a significant amount of fibrosis or necrosis. These data suggested that reversal of asynergy in response to nitroglycerin signifies reversibly ischemic or normal myocardium. On the other hand, Komer et al[28] found no improvement in ischemic wall thickening abnormalities in any portion of the ischemic zones. The myocardial responsiveness of the border zone to nitroglycerin is still in dispute.

Myocardium with partial or patchy necrosis would be expected to have a complex functional response to nitroglycerin, because of interregional tethering[29] and vascular communication. Moreover, nitroglycerin has both beneficial and deleterious effects on ischemic myocardium, depending primarily on the resulting increase in heart rate and reduction in systemic pressure.[3,17,27,30]

The present study related regional myocardial necrosis to myocardial function. We found that nitroglycerin could improve wall motion abnormalities in ischemic zones, and that the region which did not respond to nitroglycerin correlated well with the extent of measured myocardial necrosis (Fig. 6).[22,31]

Limitations of our study: There are evident limitations in this study. Thus, although we carefully matched 2-D echocardiographic cross sections with equivalent excised LV slabs, using every available cardiac muscle landmark for structural reference, the 2 sections may not be quite the same. It is also necessary to recognize that pathologic slabs may change their size and become somewhat distorted. The relatively small number of segments studied and high variability in systolic wall thickening measurements (Table II) may limit definite statistical evaluation. Thus, the discrepancy between systolic fractional area change and systolic wall thickening noted in the group of 41 to 60% necrosis (Fig. 2) may be due to a small sample number. Our present study could not ascertain the ultimate fate of nitroglycerin-potentiated segments, nor could it exclude potential viability of segments that failed to be potentiated early after coronary occlusion, but might have been treated at that time by reperfusion.

Clinical applications: This study indicates that 2-D echocardiography of LV segments during brief periods of nitroglycerin infusion can help characterize the functional reserve of myocardium during acute ischemia in dogs. The experimental data may not be simply applicable to the human subject. Thus, myocardial response to nitroglycerin in patients with chronic coronary artery disease could be affected by collateral circulation, old fibrosis, and the number of vessels involved. Nevertheless, our experimental data suggest that myocardial areas that improve function by nitroglycerin testing may be judged to be sufficiently viable to allow rational therapy. Thus, 2-D echocardiographic nitroglycerin testing during treatment of patients with acute myocardial infarction may prove useful for assessment of interventions and their effectiveness.

Nuclear Magnetic Resonance Imaging of Acute Myocardial Infarction in Dogs: Alterations in Magnetic Relaxation Times

CHARLES B. HIGGINS, MD, ROBERT HERFKENS, MD, MARTIN J. LIPTON, MD, RICHARD SIEVERS, BS, PHILIP SHELDON, BA, LEON KAUFMAN, PhD, and LAWRENCE E. CROOKS, PhD

Nuclear magnetic resonance (NMR) imaging was used to study 24-hour-old acute myocardial infarctions in 8 dogs. Images and measurements of excised hearts were obtained in a 6.5 ml bore-resistive NMR imager (0.35 Tesla). Spin echo NMR imaging in each instance demonstrated the area of infarction as a region of increased signal intensity compared with that in normal myocardium. The T1 and T2 values of the area of infarction were greater than those of normal myocardium in all dogs. For each dog the T1 value was greater for the infarct region; however, the group mean value for T1 (ms) of the infarct region (728 ± 94) was not significantly greater than that for the normal region (650 ± 87). The T2 value (ms) was discriminate for all dogs, and the mean value for the infarct region (48 ± 2) was significantly different ($p < 0.01$) from the value for normal myocardium (42 ± 1). The percent water content of the infarct (79 ± 1%) was significantly greater ($p < 0.01$) than that of normal regions (76 ± 1%). The linear relationship between T2 value and percent water content showed a good correlation coefficient ($r = 0.90$; $p < 0.01$).

NMR imaging detects acute myocardial infarction as a positive image without contrast media. Increased signal intensity of the infarct is related to increased hydrogen density and increased T2 relaxation time.

Coronary heart disease is the major cause of morbidity and mortality in industrialized countries. Nuclear magnetic resonance (NMR) imaging has some intrinsic advantages for the study of the cardiovascular system and myocardial disease. Because flowing blood generates little or no NMR signal, there is high natural contrast between the lumen and walls of blood vessels and cardiac chambers,[1,2] which is attained without the use of contrast medium. In addition, tissue characterization can be attained from analysis of magnetic relaxation times (T1 and T2) of tissues.[3,4]

Magnetic relaxation times of tissues have been found to be altered by pathologic processes,[3,4] particularly processes that increase the water content of tissues.[5,6] Myocardial ischemic damage is associated with predictable increases in regional myocardial water content.[6,7] In a recent study the relaxation times of normal and infarcted myocardial samples were measured using an inversion recovery technique, and a significant increase was found in T1 relaxation times of infarcted myocardium.[6] However, the only previously reported study that attempted to image ex situ infarcted hearts with NMR failed to discriminate infarcted from normal myocardium unless contrast media were administered.[8] The area of nonperfusion was only demonstrated by using a paramagnetic contrast medium (manganese).

This study was undertaken to determine whether NMR imaging techniques more sensitive to myocardial edema would result in the detection of acute myocardial infarction (MI) without contrast media and to define the alterations in magnetic relaxation times associated with myocardial ischemia injury. The relation between changes in myocardial relaxation times and myocardial water content also were assessed.

TABLE I Individual Values for T1, T2, and Percent Water Content

	Infarcted Myocardium			Normal Myocardium		
Dog	T1 (ms)	T2 (ms)	Water (%)	T1 (ms)	T2 (ms)	Water (%)
1	694	45.4	78.4	620	42.8	76.7
2	640	45.7	77.5	549	40.8	76.3
3	599	48.8	78.5	538	43.0	75.2
4	803	52.0	79.2	710	40.2	75.9
5	876	49.2	78.2	771	42.3	75.9
6	758	50.5	78.6	713	43.5	77.3
Mean	728.3	48.4	78.6	650.2	42.1	76.2
SD	94.8	2.4	0.7	87.4	1.2	0.6

SD = standard deviation.

Methods

Eight adult mongrel dogs (weighing 15 to 21 kg) were used in this study. Six dogs underwent operative ligation of the left anterior descending coronary artery (distal to the first septal branch) and 2 dogs served as sham animals. Twenty-four hours after coronary arterial ligation the dogs were killed by administering pentobarbital. NMR imaging was performed 60 to 90 minutes after cardiectomy.

The excised hearts were placed within the 6.5 cm aperture of the small animal NMR imager. This is a resistive NMR imager with a field strength of 0.35 Tesla (15 MHz hydrogen resonant frequency). Five simultaneous cross-sectional levels (5 mm in thickness) were imaged in 6.5 minutes. Spatial resolution was 1.5 mm × 1.5 mm × 4 mm. The hearts were imaged from apex to the base of the heart using 2 contiguous image volumes each consisting of 5 contiguous 5-mm transverse (axial) images.

The NMR imaging technique was the spin echo sequence described in detail previously.[9] At each cross-sectional level 4 different images were obtained by using a combination of 2 pulse sequence intervals (500 and 1,000 ms) and 2 echo delay times (28 and 56 ms).

Because the area of MI was most clearly discernible on images obtained with a 1,000-ms pulse interval and 56-ms echo-delay time (1,000/56), the regions of interest for T1 and T2 relaxation times were outlined on the 1,000/56 image. The T1 and T2 relaxation times were determined by a method described previously.[3] For each heart the T1 and T2 relaxation times were average values determined from 6 separately defined regions of interest. The regions of interest were manually drawn over the anterior wall of the left ventricle (infarct) or over the posterior wall (normal myocardium). The regions of interest over the anterior and posterior walls were equivalent in area. For the sham animals regions of interest were determined over the same 2 areas.

After completion of the imaging procedure the hearts were sliced transversely (from apex to base) at 10 mm intervals. The perimeter of each myocardial slice and the area of gross MI was traced on clear film overlays for subsequent comparison with NMR images. The area of gross MI was clearly visible on each myocardial slice. Incubation of the myocardial slice in a histochemical stain was not used to further define the MI in this study because of the desire to measure true wet and dry weights of myocardial samples. Moreover, 24-hour-old infarcts are clearly defined without histochemical staining. For each heart, 5 myocardial samples were cut from the center of the infarct and 5 from the normal posterior wall of the myocardial slices. With the sham hearts 5 samples were obtained from both the anterior and posterior walls of the myocardial slices. After blotting dry these samples were weighed (wet weight) on an Ainsworth balance. The samples were weighed again after dessication to a constant dry weight in a dessicating oven (HEET-CAB, Lab-Line Instruments) for 48 to 72 hours. The percent water content was calculated as [(wet weight − dry weight)/wet weight] × 100%. The percent water content reported for the infarct or the normal myocardium of each heart represents the mean value of 5 individual tissue samples.

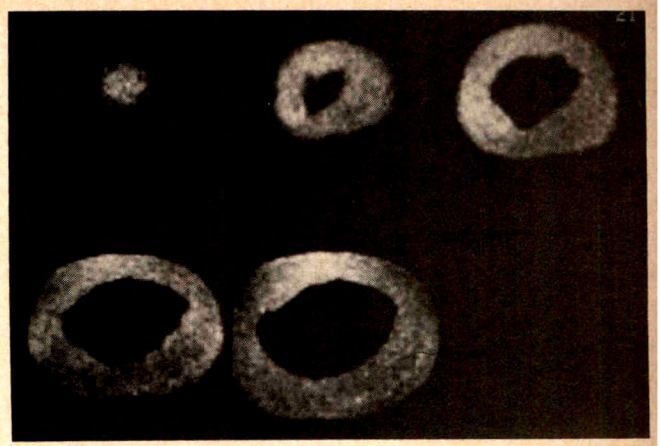

FIGURE 1. Sequential cross-section nuclear magnetic resonance images extending from the apex to mid-portion of the left ventricle in a dog at 24 hours after ligation of the left anterior descending coronary artery. The high intensity area (**increased brightness**) involves almost the entire cross-sectional area (**left upper slices**) in the 2 caudal sections. On the most cranial slice the high intensity region is confined to the anterior wall. Images are viewed from above.

Data analysis and statistics: For each infarcted heart and sham heart the percent differences in magnetic relaxation times (T1 or T2) between infarcted and normal myocardium were calculated. In this manner each animal served as its own control for defining changes in relaxation times with the ischemic intervention. The following formula was used for these calculations: Percent difference T1 (or T2) = ([T1 (or T2) infarct − T1 (or T2) normal]/[T1 (or T2) normal]) × 100%.

The group data for T1, T2, and percent water content for the infarcted and normal regions of infarcted hearts are reported as mean values ± standard deviation. The data for sham animals are presented as a mean value and range because only 4 values (anterior and posterior wall from 2 animals) were obtained. Again, the T1 and T2 values (for each individual animal) represents the mean of values calculated

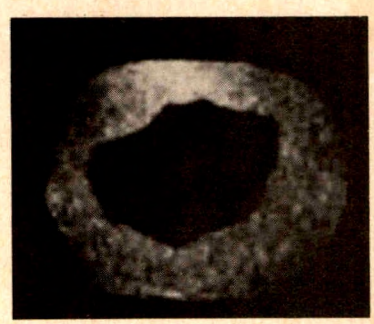

FIGURE 2. Cross-sectional NMR image through the mid-portion of the left ventricle shows a high intensity area in the anterior wall of the left ventricle. Image is viewed from above.

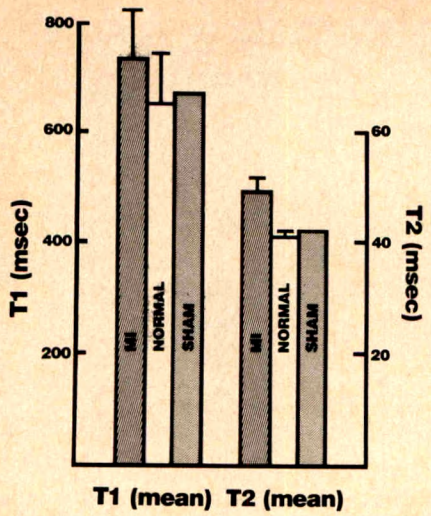

FIGURE 3. Block diagram showing the mean values ± standard deviation for T1 and T2 values for infarcted myocardium (MI) and normal myocardium (NORMAL) of dogs with 24-hour-old myocardial infarctions. The value for sham animals is also shown.

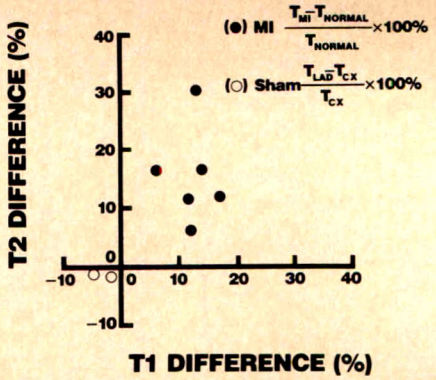

FIGURE 4. Percent differences in T1 and T2 values between normal and infarcted myocardium plotted for each of the 6 dogs with infarcts. Similarly, the percent differences for relaxation times of the left anterior descending coronary artery (LAD) and circumflex (CX) distribution are plotted for the 2 sham dogs.

from 6 separately defined regions of interest within the infarcted or normal myocardium (as previously described).

Differences in the mean values for T1, T2, and percent water content between infarcted and normal myocardium were compared for statistical significance using the paired *t* test. The relation between T1 or T2 and percent water content was analyzed with the least-squares fit for linear regression.

Results

Pathologic findings: Gross MI involved the anterior wall of each transverse myocardial slice caudal to the ligature at postmortem examination in all 6 dogs. The infarct extended from the ligature on the proximal left anterior descending coronary artery to the apex of the left ventricle. Almost the entire circumference of the most caudal (apical) slice consisted of infarcted tissue. In some animals the infarct also extended into the lateral wall or the anterior portion of the septal wall. The entire posterior wall and the posterior half of the septal wall were free of infarction in all animals. In the 2 sham animals, MI was absent.

The mean percent water content of infarcted myocardium (79 ± 0.7%) was significantly greater ($p < 0.01$) than that of the normal myocardium (76 ± 0.6%) (Table I). The mean percent water content of the myocardium of sham animals was 76% (range 76 to 77%). The percent water content in the area of distribution of the left anterior descending artery was nearly identical to that in the myocardium supplied by the circumflex coronary artery in the 2 sham animals.

NMR image of acute myocardial infarction: The NMR intensity of the area of MI was perceptively increased on NMR images in all 6 dogs. In conformity with gross pathologic findings, the region of increased intensity always involved the anterior segment (Fig. 1 and 2) and most of the circumference of the 2 caudal (apical) slices (Fig. 1). There was no area of increased signal intensity in the 2 sham animals.

T1 and T2 relaxation times: When considering the animals as a group, the mean value for T1 relaxation times of infarcted myocardium (728 ± 95 ms) was not significantly greater than the value for normal myocardium (650 ± 87 ms) (Fig. 3). There was a wide range of T1 values for infarcted and normal myocardium, and overlap of individual T1 values between infarcted and normal myocardium (Table I). The T1 value of the infarcted myocardium was greater than that of normal myocardium for each individual animal. The percent differences in T1 values of infarcted compared with normal myocardium, when each dog was used as its own control, are depicted in Figure 4.

The mean value for T2 relaxation time of infarcted myocardium (48 ± 2 ms) was significantly greater ($p < 0.01$) than that of normal myocardium (42 ± 1 ms) (Fig. 3). There was a narrow range of T2 values for normal myocardium (40 to 43 ms) and no overlap of individual values between the infarcted and normal groups (Table I). The percent differences in T2 values of infarcted compared with normal myocardium when each dog was used as its own control are depicted in Figure 4.

No significant relation was noted between T1 relaxation and the water content of myocardium ($r = 0.47$; difference not significant) (Fig. 5). A good correlation ($r = 0.90$, $p < 0.01$) was seen in the linear relation between T2 values and percent water content of myocardial samples (Fig. 6).

Discussion

Regions of acute MI showed increased signal intensity on NMR images with use of the spin echo technique. With the spin echo technique, signal intensity is determined by hydrogen density as well as by the T1 relaxation time and T2 relaxation times of the tissue. Intensity increases with greater hydrogen density, shortening of T1, and lengthening of T2 relaxation time. The spin echo technique tends to accentuate T2 differences between tissues compared with some other techniques, like inversion recovery, which emphasize

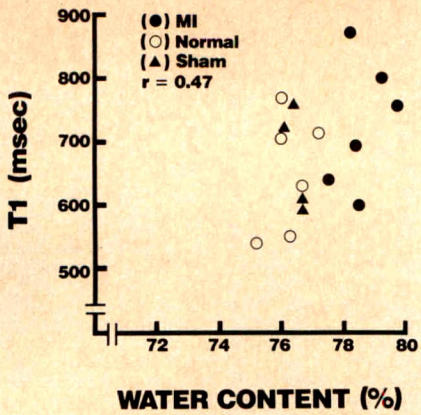

FIGURE 5. T1 relaxation times plotted against the percent water content. Values are given for infarcted and normal myocardium (MI) of infarcted dogs and for the left anterior descending artery and circumflex areas of the 2 sham animals.

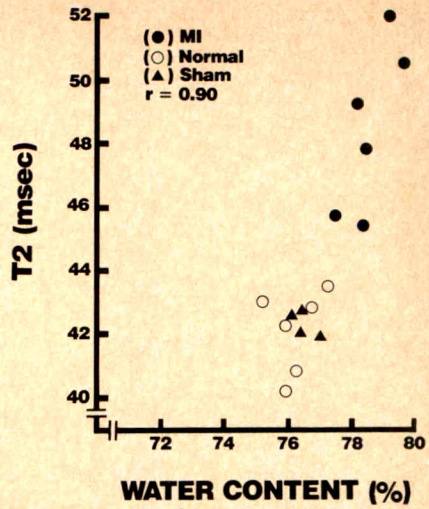

FIGURE 6. T2 relaxation times plotted against the percent water content. Format is the same as for Figure 5.

T1 differences. The current study indicated that both the T1 and T2 values of infarcted myocardium were increased compared with values of normal myocardium. The increase of T1 value would tend to decrease the signal intensity of NMR images. Consequently, the increase in intensity observed in the area of infarcted myocardium indicates preponderance of the influence of a prolonged T2 relaxation time and increased hydrogen density in the formation of the spin echo images.

Two earlier reports demonstrated increases in T1 relaxation time of ischemically injured myocardium that parallel increases in myocardial water content. The current study did not find a close relation between T1 and myocardial water content.[6,10] Previous studies[3,11] and the current one also found increased T2 relaxation time in abnormal tissues, particularly edematous tissues.

The finding of a significant increase in T2 values of ischemically damaged myocardium is unique to this study, as is the observation that the area of myocardial damage shows an increase in NMR signal intensity. Previous reports have indicated either that the ischemically damaged myocardial region is represented by a poorly defined area of diminished signal intensity on NMR images[12] or that the ischemically damaged area can only be recognized as a perfusion defect after intravenous administration of a paramagnetic substance (manganese).[8] The diametric conclusions of the current report and previous ones[8,9] may be a consequence of a difference in NMR imaging techniques because the spin echo technique tends to accentuate T2 differences as well as hydrogen density of tissues.[13] The importance of the NMR imaging characteristics of ischemically damaged myocardium with use of the spin echo technique (as applied in the current study) is that the pathology is represented as a positive image (increased intensity) and infarcted myocardium is discriminated from normal myocardium without the need for contrast media.

The T2 relaxation times of normal and infarcted myocardium also were linearly related to local water content. In fact, there was a greater correlation for T2 values and water content than there was for T1 value and water content as found in previous studies.[6,10] Moreover, there was a sharp boundary between the ranges of T2 values of infarcted and normal myocardium. This contrasted with the overlap of individual T1 values of normal and infarcted myocardium among the group of animals.

The findings in this study are consistent with data obtained in a rat model of muscle infarction.[11] The muscle of the infarcted hind leg showed significant prolongation of T1 and T2 relaxation times compared with the normal contralateral leg. The T2 relaxation rates displayed closer relationship to the percent water content of the muscles than the T1 relaxation rates.

The current study as well as a number of previous studies reveal the advances in diagnosis offered by NMR imaging; normal tissues and pathologic processes may be characterized by their relative T1 and T2 relaxation processes.[3–6,10,11] Optimistic conjecture would envision early assessment of the effects of therapeutic intervention by defining T1 and T2 values using NMR imaging of ischemic processes. With proton NMR imaging, tissue characterization must be shown to have clinical efficacy because the anatomic information provided by NMR imaging is similar to that achieved by computed tomography and ultrasonography. A distinct advantage of NMR imaging in ischemic heart disease and other cardiovascular diseases is the ability to define internal cardiac topography without the need for contrast media. This is particularly important in acute myocardial ischemia and infarction because currently used contrast media have potentially deleterious hemodynamic and electrophysiologic effects.[14]

The application of NMR imaging to heart disease is complicated by cardiac and respiratory motion. Motion degrades NMR images by decreasing signal intensity rather than by introducing artifacts as occurs with computed tomography. The recent demonstration of excellent NMR images of the heart with use of cardiac

gating by 2 groups[15,16] indicates the early feasibility of clinical NMR imaging for the evaluation of heart disease. A technique for rapid acquisition of NMR images within a 40- to 50-ms period may also be useful for NMR imaging of the heart.[17]

Effects of Coronary Occlusion on Flow in the Distribution of a Neighboring Stenotic Coronary Artery in the Dog

JEFFREY S. SCHWARTZ, MD, JAY N. COHN, MD, and ROBERT J. BACHE, MD

The effect of left anterior descending coronary artery (LAD) occlusion on flow through a severely stenotic left circumflex artery (LC) was studied in 19 open-chest dogs. In 8 dogs (Group 1) aortic pressure, distal circumflex pressure, circumflex flow, and heart rate were measured. In the absence of an LC stenosis, LAD occlusion resulted in an increase in LC flow from 32 ± 3 to 41 ± 5 ml/min ($p < 0.001$). In the presence of a severe LC stenosis produced with a snare, LAD occlusion resulted in a decrease in distal LC pressure (54 ± 2 to 30 ± 1 mm Hg; $p < 0.001$), an increase in resistance across the LC stenosis (1.8 ± 0.2 to 3.5 ± 0.4 units; $p < 0.001$) and a decrease in flow through the LC (24 ± 2 to 20 ± 2 ml/min; $p < 0.001$). Aortic pressure did not change significantly (94 ± 3 to 93 ± 3 mm Hg) and heart rate increased slightly (90 ± 5 to 104 ± 5 beats/min; $p < 0.001$). LAD occlusion, therefore, increased the severity of the LC stenosis and resulted in a decrease in LC flow. The decrease in intraluminal pressure distal to the LC stenosis, and thus in the stenotic segment itself, may have resulted in passive narrowing of the stenotic segment, which may have been responsible for the decrease in flow.

In 11 dogs (Group 2) the LC stenoses were produced so that anterograde flow through the stenotic LC artery did not change significantly after LAD occlusion. However, LAD occlusion resulted in a decrease in flow (measured with radioactive microspheres) to the area supplied by the stenotic LC artery (0.62 ± 0.02 to 0.50 ± 0.09 ml/min/g; $p < 0.05$), possibly because collateral flow from the LAD to the LC-dependent myocardium was interrupted. In addition, LAD occlusion resulted in selective underperfusion of the subendocardial layers of the LC-dependent area (endocardial/epicardial flow ratio from 0.89 ± 0.07 to 0.40 ± 0.10; $p < 0.005$), possibly because of a combination of a decrease in perfusion pressure distal to the stenoses (54 ± 4 to 39 ± 3 mm Hg; $p < 0.005$) and an increase in left ventricular end-diastolic pressure (from 6 ± 1 to 13 ± 2 mm Hg; $p < 0.005$).

The results of these studies demonstrate mechanisms by which myocardial ischemia may occur in the area supplied by a stenotic coronary artery if a neighboring coronary artery becomes occluded.

Many patients with acute myocardial infarction have significant stenoses in coronary arteries other than the one supplying the infarcted area.[1] In 1940, Blumgart et al[2] discussed the concept of "infarction at a distance." In this situation, myocardium in the distribution of an occluded coronary artery is dependent on collaterals from a second coronary artery. If the second artery becomes acutely occluded, infarction may occur in the collateral-dependent area which is "distant" from the area of acute occlusion.

Recently Schuster and Bulkley[3,4] reported that some patients with acute myocardial infarction had postinfarction ischemia in an area of myocardium distant from the infarcted area. These patients had atherosclerotic narrowing with superimposed thrombotic occlusion of the artery supplying the infarcted area and a severe stenosis of the artery supplying the remote ischemic area. These studies suggest that occlusion of a coronary artery may have a deleterious effect on myocardium supplied by a neighboring stenotic artery.

It has previously been shown in animal models that interventions that dilate the distal bed of a coronary artery with a severe, nonfixed stenosis result in a decrease in pressure distal to the stenosis, an increase in stenosis resistance, and a decrease in flow through the stenotic artery.[5,6] The dilation-induced decrease in pressure distal to the stenosis, and thus in the stenotic segment itself, may cause partial collapse of the stenotic segment, resulting in the observed increase in stenosis resistance and reduction in flow.[5,6] Other interventions that dilate the distal arteriolar bed of a stenotic coronary artery might also cause a decrease in distal coronary pressure and a passive increase in stenosis resistance. Occlusion of a neighboring coronary artery could interrupt collateral flow to the myocardium supplied by

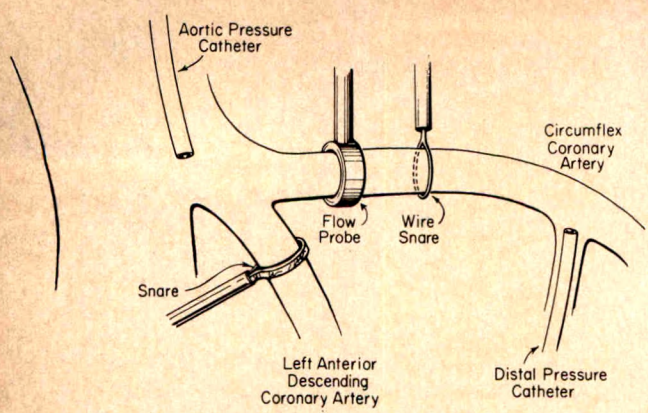

FIGURE 1. Experimental preparation.

a stenotic artery, increase the contractile force of the myocardium supplied by the stenotic artery, and increase the heart rate. All of these changes could cause dilation of the distal bed of the stenotic artery, a reduction in pressure distal to the stenosis, passive collapse of the stenotic segment, and a decrease in flow through the stenotic artery. The decrease in flow through the stenotic artery could result in ischemia distant from the myocardium supplied by the occluded artery.

Occlusion of a coronary artery could also cause a decrease in total flow to myocardium supplied by a neighboring stenotic artery simply by interrupting collateral flow to the area. Furthermore, subendocardial perfusion could be impaired by the combination of a decrease in pressure distal to the stenosis caused by distal bed dilation and an increase in left ventricular diastolic pressure.[7–9] Both a decrease in collateral flow and a selective decrease in subendocardial flow could result in ischemia in an area of myocardium supplied by a stenotic artery distant from an area of complete coronary occlusion.

This study, therefore, was performed to evaluate these potential mechanisms of ischemia in the distribution of a stenotic coronary artery when a neighboring coronary artery is occluded.

Methods

The studies were performed in 19 open-chest dogs anesthetized with intravenous alpha chloralose (100 mg/kg) and intramuscular morphine (2 mg/kg). The mean weight of the dogs was 24 ± 1 kg (range 21 to 32 kg). Respiration was controlled with a Harvard respirator pump through a cuffed endotracheal tube. A left thoracotomy was performed. The proximal portion of the left circumflex coronary artery (LC) was dissected free and was instrumented as shown in Figure 1. A PE 50 catheter was inserted into a branch of the LC for measurement of distal coronary arterial pressure. A PE 200 catheter was advanced through the femoral artery into the ascending aorta for measurement of aortic pressure. Statham P23ID pressure transducers were used. Before each experiment, each transducer system was calibrated with a mercury manometer.

The stenosis was produced with an external wire snare placed around the LC proximal to the coronary pressure catheter. The snare consisted of soft wire attached through polyethylene tubing to a machinist's micrometer so that precise adjustments of the degree of arterial narrowing could be made. A 2.0 or 2.5 mm flow probe was placed around the LC proximal to the snare. A Statham P2202 electromagnetic flowmeter was used. Distal LC pressure was monitored while the flow probe was put in place. The size of the probe was chosen so that it gave a good quality flow signal without changing LC pressure distal to the probe. Zero flow, obtained by transient complete occlusion of the LC, was checked frequently during the course of each experiment.

A portion of the mid left anterior descending artery (LAD) was also dissected free. A snare consisting of umbilical tape passed through polyethylene tubing was placed around the artery. Complete occlusion of the LAD was accomplished by tightening this snare.

All animals received an infusion of 1 mg/min of lidocaine throughout the procedure. Extra boluses of lidocaine were administered as necessary to control ventricular arrhythmias.

The dogs were classified into 2 groups. In Group 1, consisting of 8 dogs, the effect of occlusion of the LAD on anterograde flow through the stenotic LC was studied. Aortic pressure, distal LC pressure, LC blood flow, and lead II of the electrocardiogram were recorded before and after complete occlusion of the LAD. The LAD was first temporarily occluded in the presence of a normal LC. The LC was then progressively narrowed by tightening the wire snare, after which the LAD was again occluded. This procedure was repeated until the LC stenosis was severe enough so that occlusion of the LAD resulted in a decrease in flow through the LC.

In Group 2, consisting of 11 dogs, regional myocardial blood flow was measured with radioactive microspheres. The experimental preparation was identical to that previously described except for the addition of a left atrial catheter through which the microspheres were injected and a fluid-filled catheter inserted through the apex of the left ventricle for left ventricular pressure measurement. In each dog regional myocardial blood flow was measured before and after complete occlusion of the LAD in the presence of a normal LC and again in the presence of a severely stenotic LC. So that the order of the experiments did not affect our results, normal LC arteries were studied first in some dogs and stenotic arteries were studied first in others. The LC stenoses were produced by tightening the wire snare. The purpose of this portion of the study was to evaluate the effect of LAD occlusion on transmural flow in the distribution of a stenotic LC artery when anterograde flow through the stenotic LC did not change. In the total group of dogs there was no significant change in flow through the stenotic LC after LAD occlusion.

In the entire group of dogs, the LC stenosis was stable for a mean of 10 ± 2 minutes before LAD occlusion. The LAD was occluded for a mean of 4 ± 0.4 minutes. Hemodynamic measurements were recorded a mean of 83 ± 7 seconds after the onset of LAD occlusion.

Fifteen μm diameter microspheres (3M Company) were used to measure regional myocardial blood flow. They were diluted in 10% low molecular weight dextran and approximately 5×10^6 microspheres were injected. Before injection the microspheres were mixed in a vortex agitator and an ultrasonic bath for at least 15 minutes. In each study, microspheres were used which were labeled with 4 of the following isotopes: iodine-125, cerium-141, cobalt-57, niobium-95, scandium-46, strontium-85, tin-113, or chromium-51. The microsphere suspension was injected into the left atrium over a 15-second period and the atrial line was flushed with 10 ml of isotonic saline solution. Beginning simultaneously with the microsphere injection and continuing for 90 seconds, a ref-

erence sample of arterial blood was drawn from the aortic catheter at a constant rate of 15 ml/min.

At the end of the experiment 10 ml of Evans blue dye was injected into the LC at systemic pressure. The animals were then killed and the hearts were removed, weighed, and fixed in 10% buffered formalin. The posterior papillary muscle region was supplied by the LC in each dog as documented by its blue staining. This region was therefore taken to represent the myocardium under study. This region was divided into 4 transmural layers of equal thickness, with layer 1 being the layer closest to the epicardium and layer 4 being the layer closest to the endocardium. The papillary muscle was called layer 5. Similar myocardial specimens were taken from the anterior wall in the distribution of the LAD and were divided into 4 transmural layers of equal thickness, with layer 1 being closest to the epicardium and layer 4 being closest to the endocardium. All myocardial sections were weighed and placed in vials for counting.

All sections were counted in a Packard model 5912 gamma spectrometer with a multichannel analyzer at window settings selected to correspond to the peak energies of each radionuclide. The activities recorded in each energy window were corrected for background activity and for overlapping counts contributed by the accompanying isotopes with a digital computer. Blood flow was calculated by using the reference arterial blood sample during the injection of microspheres. Knowing the rate of withdrawal of the reference sample (Qr) and the radioactivity in the reference sample (Cr), and assuming that the ratio of flow and radioactivity is identical in all organs because uniform mixing of microspheres with blood occurs during passage through the left ventricle, myocardial blood flow (Qm) was determined by measuring the myocardial radioactivity (Cm) and calculating $Qm = Qr \cdot Cm/Cr$. Myocardial blood flow (ml/min) was divided by the corresponding sample weight and was expressed as ml/min/g of myocardium.

Hemodynamic measurements were recorded on a Hewlett-Packard 7758B recorder at paper speeds of 1 to 25 mm/s. Mean resistance across the stenotic segment was calculated using the formula $R = (P1 - P2)/Q$ and was expressed in resistance units (mm Hg/ml/min), where P1 = mean aortic pressure, P2 = mean distal LC pressure, and Q = mean LC coronary blood flow. Distal LC resistance was calculated by dividing mean distal LC pressure by LC flow.

All data are shown as mean values ± the standard error of the mean. Significance of the differences for the hemodynamic data was determined by Student's *t* test for paired observations.[10] Significance of differences for the microsphere flow data was determined by 2-way analysis of variance.[10]

Results

In the dogs in Group I, the LAD was first occluded in the presence of a normal LC. The results are shown in Table I, and an example is shown in Figure 2. As seen in Table I, there was a small increase in heart rate and a small decrease in aortic and distal coronary pressure. Mean blood flow through the LC increased from 32 ± 3 to 41 ± 5 ml/min.

As a stenosis was applied to the LC and was made more severe, there was a smaller increase in blood flow through the LC in response to LAD occlusion. The effects of LAD occlusion on the hemodynamics of a severely stenotic LC are shown in Table I and Figure 3. As shown in Table I, there was a small increase in heart rate and aortic pressure did not change significantly. The distal coronary pressure decreased, however, and the pressure gradient across the stenosis increased. There was also a marked and significant increase in stenosis resistance, and flow through the stenotic artery actually decreased significantly.

In the 11 dogs in Group 2, regional myocardial blood flow was measured before and after LAD occlusion in the presence of a normal LC and in the presence of a stenotic LC. The stenoses were produced so that minimal changes in anterograde flow would occur through the stenotic LC in response to LAD occlusion. In each dog complete LAD occlusion was confirmed by the finding of a decrease in flow from 0.61 ± 0.05 to 0.05 ± 0.01 ml/min/g in the region of the anterior LV wall after LAD occlusion.

The hemodynamic effects of LAD occlusion in dogs in Group 2 in the absence of a LC stenosis are shown in Table II. The data are similar to those dogs without a stenosis in Group 1.

In the myocardial region supplied by the normal LC, regional flow measured with radioactive microspheres also increased after LAD occlusion (0.85 ± 0.04 to 1.05 ± 0.07 ml/min/g, $p < 0.05$). The change in flow in each

Mean pressures and flow are shown on the **left** and **right** and phasic pressures and flow in the **center.** Aortic and distal circumflex pressures decreased slightly and circumflex flow increased.

transmural layer is shown in Figure 4. In the absence of a LC stenosis, the endocardial/epicardial ratio did not change significantly in response to LAD occlusion (0.86 ± 0.10 to 0.81 ± 0.11).

The hemodynamic effects of occlusion of the LAD in dogs in Group 2 in the presence of an LC stenosis are shown in Table II. As can be seen, aortic pressure did not change significantly. Both mean and diastolic coronary pressure distal to the stenosis decreased significantly. Left ventricular end-diastolic pressure increased significantly, and there was a small but significant increase in heart rate. In individual dogs, LAD occlusion resulted in a small increase or decrease in total anterograde flow through the stenotic LC, but in the total group of dogs flow did not change significantly.

The changes in transmural flow measured with microspheres in the distribution of the stenotic LC in response to LAD occlusion are shown in Figure 5. Sub-

epicardial flow did not change significantly. However, flow in subendocardial layers 4 and 5 decreased significantly. Total transmural flow to the region supplied by the LC artery decreased slightly but significantly in response to LAD occlusion (0.62 ± 0.02 to 0.50 ± 0.09 ml/min/g; $p < 0.05$). The endocardial/epicardial ratio decreased from 0.89 ± 0.07 to 0.40 ± 0.10 ($p < 0.005$).

Discussion

In the absence of LC stenosis, occlusion of the LAD resulted in an increase in LC blood flow as measured with the electromagnetic flowmeter. An increase in flow in a coronary artery in response to occlusion of an adjacent coronary artery has been described previously.[11–14] There are several possible explanations for this finding. First, when pressure in the LAD decreases as a result of occlusion, the area supplied by the occluded artery may receive collateral flow from the LC. The LC, therefore, provides flow to its own area plus additional flow to the LAD area so that flow through the LC increases.[14] Second, in our study, occlusion of the LAD resulted in a small increase in heart rate. It is likely that the heart rate change contributed to the increase in flow through the LC. Third, although it was not evaluated in this study, occlusion of the LAD may have resulted in an increased force of contraction in the remaining normally perfused myocardium. Although an initial increase in active shortening of the normal area has been observed after coronary occlusion,[15] this has not always been found.[16] As a result of any or all of these factors, LAD occlusion resulted in a decrease in distal LC resistance and an increase in flow through the normal LC.

In the presence of a severe LC stenosis (Group 1), the results were very different. Occlusion of the LAD resulted in a decrease in flow through the stenotic LC. As

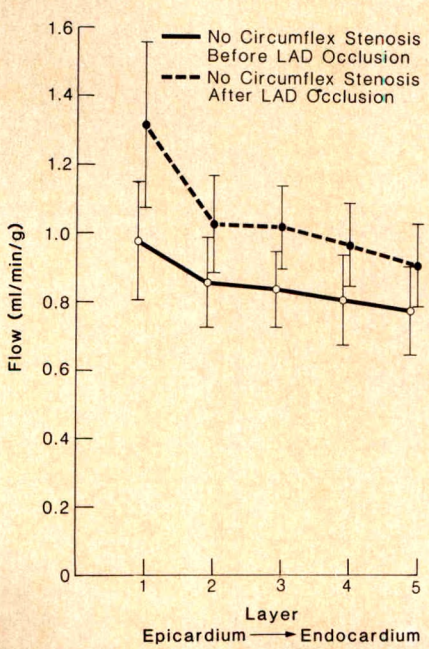

FIGURE 4. Mean left ventricular myocardial blood flow to 5 transmural layers of the posterior papillary muscle region before and after left anterior descending (LAD) coronary artery occlusion in the absence of a circumflex stenosis.

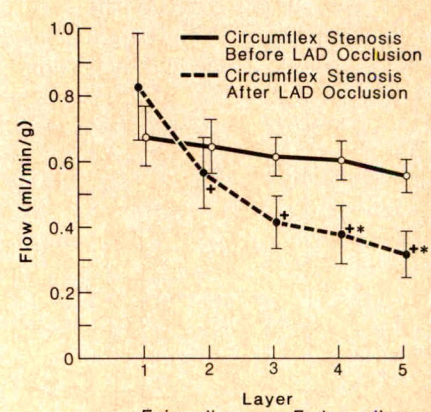

FIGURE 5. Mean left ventricular myocardial blood flow to 5 transmural layers of the posterior papillary muscle region before and after left anterior descending (LAD) coronary artery occlusion in the presence of a circumflex stenosis. * $p < 0.05$ compared with before occlusion; † $p < 0.05$ compared with layer 1.

shown in Table I, there was a decrease in distal LC resistance and an increase in stenosis resistance, suggesting that the increase in the severity of the stenosis led to the decrease in flow through the LC.

The mechanisms responsible for dilation of the distal bed of the stenotic LC in response to LAD occlusion are similar to those just described for the normal LC. In addition, in the presence of an LC stenosis severe enough to produce a pressure gradient, the LAD may have supplied collateral flow to the myocardium in the LC distribution. Occlusion of the LAD would interrupt this collateral flow, perhaps contributing to compensatory dilation of the LC arteriolar bed.

There are two possible explanations for the increased severity of the LC stenosis after LAD occlusion. The first is active constriction of the stenotic segment. Occlusion of the LAD could result in increased sympathetic activity which could possibly result in active constriction of the LC. It has previously been shown, however, that active constriction of an artery with an external snare stenosis has little hemodynamic effect.[17] Therefore, this explanation for the increased severity of the LC stenoses seems unlikely.

The second possible explanation is a passive increase in stenosis resistance. In the presence of LC stenosis, LAD occlusion resulted in dilation of the distal LC bed as evidenced by the decrease in distal LC pressure and the decrease in distal LC resistance. Previous studies have shown that in the presence of a severe coronary stenosis, dilation of the distal coronary bed can result in a decrease in flow through the stenotic coronary artery.[5,6] A similar mechanism may be responsible for the findings in the present study. Occlusion of the LAD resulted in dilation of the distal LC bed and a decrease in distal LC pressure. Pressure in the stenotic segment itself would also be expected to decrease.[18] This decrease in intraluminal pressure may then result in passive narrowing of the stenotic segment. A passive decrease in stenosis caliber could increase stenosis resistance sufficiently to cause a decrease in flow.

It has previously been shown that a decrease in intraluminal pressure leads to an increase in resistance across nonfixed stenoses but not across fixed, rigid stenoses.[19,20] Therefore an increase in stenosis resistance and a decrease in flow through a stenotic coronary artery in response to occlusion of a neighboring coronary artery should occur only if the stenosis is compliant and capable of passively narrowing. It has previously been shown that stenoses produced with external snares are compliant.[20]

The animals in Group 2 differed from the animals in Group 1 in that the stenoses in Group 2 were adjusted so that occlusion of the LAD did not result in a significant change in mean flow through the stenotic LC. Although anterograde flow through the LC did not change, total flow to the area of myocardium supplied by the LC as measured with radioactive microspheres decreased from 0.62 ± 0.02 to 0.50 ± 0.09 ml/min/g ($p < 0.05$). This decrease in regional flow may have been due to the fact that flow through collateral vessels from the LAD to the LC region was cut off by LAD occlusion.

In addition, occlusion of the LAD resulted in a transmural redistribution of blood flow away from the subendocardium in the region supplied by the stenotic LC. There was no significant change in flow to the subepicardial layer and a significant decrease in flow to the subendocardial layers. This redistribution of flow most likely resulted from a combination of several factors. In the presence of a flow-limiting coronary stenosis, the proportion of flow occurring during systole increases.[21] Extravascular compression during systole results in a transmural myocardial flow gradient so that the subendocardial layers are underperfused.[22,23] In addition, dilation of the coronary arteriolar bed distal to the stenosis results in a decrease in coronary pressure distal to the stenosis. Previous studies have suggested that an intramyocardial pressure gradient increasing from subepicardium to subendocardium may exist during diastole.[24] An intrinsic gradient of coronary vascularity may also exist favoring blood flow to the endocardium during diastole.[25] However, in the presence of a flow-limiting coronary stenosis, as pressure distal to the stenosis decreases, vasodilation may occur which limits the ability of the coronary resistance vessels to further dilate and maintain the vascular resistance gradient favoring the subendocardium.[26] In this situation, when the vessels cannot further dilate and the pressure within the vessels is very low, the extravascular tissue pressure may impede subendocardial blood flow.

Left ventricular end-diastolic pressure increased modestly after LAD coronary artery occlusion. It has been shown that an increase in preload selectively reduces flow in the inner layers of the heart, probably because of an increase in intramyocardial tissue pressure.[7,8] In the present study, the increase in left ventricular diastolic pressure may have increased extravascular myocardial tissue pressure, an effect that would be most marked in the subendocardial layers and would further impede subendocardial flow.

LAD occlusion resulted in an increase in heart rate in this portion of the study which averaged 25 beats/min. In the presence of a dilated coronary bed, tachycardia can also result in a redistribution of flow away from the subendocardium.[27] Although the increase in heart rate in the present study was relatively small, it may have contributed to the redistribution of blood flow.

In summary, the present data demonstrate that occlusion of a coronary artery can cause a decrease in flow to the area supplied by a neighboring stenotic artery in 3 ways. First, coronary occlusion may cause a decrease in anterograde flow through the stenotic artery because of a passive increase in stenosis resistance. Second, occlusion of a coronary artery can result in a decrease in subendocardial flow to the area supplied by the neighboring stenotic artery. Finally, it is possible that occlusion of a coronary artery may interrupt collateral flow to the myocardium supplied by a neighboring stenotic artery. All of these mechanisms could potentially cause ischemia distant from an area of total coronary occlusion.

Roles of the Right Ventricular Free Wall and Ventricular Septum in Right Ventricular Performance and Influence of the Parietal Pericardium During Right Ventricular Failure in Dogs

MASATO TANI, MD

The roles of the right ventricular (RV) free wall and ventricular septum in RV performance were studied in the canine heart. The parietal pericardium was kept intact. Acute ischemia of the RV free wall from right coronary ligation decreased the RV stroke work index more than did that of the ventricular septum from the septal branch of the left coronary artery ligation (41 and 23%, respectively, $p < 0.01$). The response of the RV stroke work index to acute volume loading was also decreased. Left ventricular dysfunction was detected only with ventricular septal ischemia. Combined RV free wall and ventricular septal ischemia produced more severe and predominant RV dysfunction with disproportionate elevation of RV end-diastolic pressure. After combined ischemia, pericardiotomy improved the RV stroke work index as well as the left ventricular stroke work index (40 and 27%, respectively, $p < 0.05$), although the increase in RV stroke work index was greater than in left ventricular stroke work index ($p < 0.05$).

The results of this study suggest that (1) the RV free wall has a more important role than the ventricular septum in RV performance, (2) predominant RV failure can be induced experimentally after combined RV free wall and ventricular septal ischemia, and (3) the pericardium has a restrictive effect on the damaged and dilated right ventricle.

It has been reported that experimental destruction of the right ventricular (RV) free wall does not produce RV failure in the absence of RV overloading.[1–3] In contrast, patients with inferior myocardial infarction may have signs of predominant RV failure, and the ventricular septum (VS) is usually involved in addition to the RV free wall.[4–7] This involvement of the VS may be the major difference between clinical RV infarction and experimental RV destruction. Another difference which could affect RV function is the opened parietal pericardium in previous experiments. Further studies are indicated to clarify the separate roles of the RV free wall, VS, and pericardium in RV performance. In the present study, we attempted (1) to induce RV dysfunction under acute RV free wall and ventricular septal ischemia, (2) to clarify the roles of the RV free wall and VS in RV performance, and (3) to demonstrate the influence of the parietal pericardium on the function of the severely damaged and dilated right ventricle.

Methods

Fifteen mongrel dogs weighing 15 to 27 kg were anesthetized with pentobarbital (15 mg/kg, intravenously). The dogs were intubated and ventilated with a respirator (Harvard Apparatus). After a median sternotomy and left thoracotomy, the heart was exposed. Two small incisions were made in the pericardium at the base of the aorta for inserting sutures to ligate the right coronary artery, the septal branch of the left coronary artery, or both. The rest of the pericardium was kept intact. Heart rate was kept constant by right atrial pacing at the rate of 120 beats/min after sinoatrial nodal destruction. An electromagnetic flow probe (Nihon Koden) was placed around the root of the aorta through pericardial incisions. Blood pressure in the left ventricle, aorta, right ventricle, and pulmonary artery was measured through fluid-filled catheters and pressure transducers (Statham P23Db). All recordings were performed with an 8-channel recorder (Nihon Koden

WT 685 G). The first derivative of left ventricular (LV) pressure (dP/dt) was obtained continuously by differentiating the LV pressure electrically. A large bore catheter placed in the right atrium was connected to a reservoir filled with blood. Preload on the right ventricle was varied by changing the height of the reservoir. Direct measurement of pulmonary arterial flow with a flow probe is technically difficult, because the pulmonary artery may be easily constricted. Therefore, the LV and RV stroke work indexes were calculated during a steady state using aortic flow. In the left ventricle, ventricular function was also evaluated by LV peak dP/dt at matched levels of LV end-diastolic pressure.

Hemodynamic study: The control recording was obtained at a RV end-diastolic pressure of 4 mm Hg. Then, bilateral ventricular function curves were produced. RV end-diastolic pressure was changed from 3 to 8 mm Hg, while that of LV end-diastolic pressure changed from 3 to 13 mm Hg. Each end-diastolic pressure was kept constant by disconnecting the reservoir for more than 3 minutes to obtain a steady circulatory state before recording each point of the ventricular function curve. After RV end-diastolic pressure was reset at 4 mm Hg, coronary arterial ligation was done. The right coronary artery was occluded in 8 dogs and the septal branch in 7 dogs. Fifteen minutes after ligation, when hemodynamic function was stabilized, recordings at rest and during volume loading were performed using the same procedure.

In the 12 dogs who lived after these procedures, RV end-diastolic pressure was reset at 4 mm Hg and the remaining contralateral coronary artery was occluded. Four dogs died after the second coronary arterial ligation. In the remaining 8 dogs, each variable was recorded in the resting state and the same maneuver for constructing bilateral ventricular function curves was performed.

In the 8 dogs who lived after combined coronary ligation, RV end-diastolic pressure was again reset to the same value as before volume loading, but after combined ligation and with the reservoir disconnected. The parietal pericardium was removed and changes in hemodynamic variables were recorded.

Anatomic study: After completion of the hemodynamic studies, in 13 of 15 dogs the right coronary artery and septal branch were cannulated just distal to the site of ligation. Dyes (different colors of Parker ink) were injected into each vessel manually at a pressure of 100 to 120 mm Hg and the perfusion area was determined. According to Reiner's method, the resected heart was divided into the RV free wall, VS, and LV free wall.[8] Each myocardial mass was weighed.

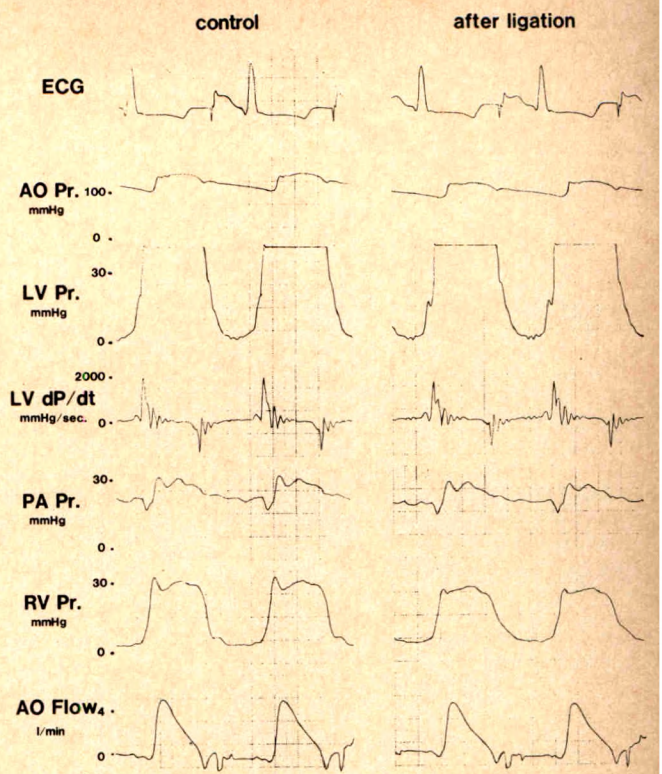

FIGURE 1. Representative hemodynamic changes of the right and left ventricles after right coronary ligation (dog 1). Right ventricular hemodynamic deterioration was observed with decreases in left ventricular end-diastolic pressure, left ventricular systolic pressure, and aortic flow, which could be due to disturbances in left ventricular filling after right coronary ligation. AO Flow = aortic flow; AO P = aortic pressure; ECG = electrocardiogram; LV dP/dt = the first derivative of left ventricular pressure; LV P = left ventricular pressure; PA P = pulmonary arterial pressure; RV P = right ventricular pressure.

Statistical analysis: In each intervention group, the means and standard deviations of the hemodynamic variables were calculated, as were their differences between the control and

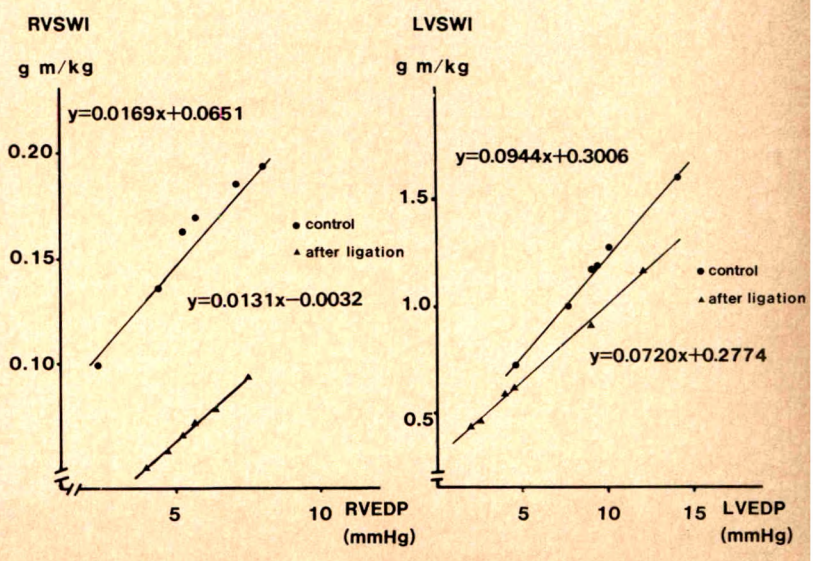

FIGURE 2. Changes in both right and left ventricular function curves after right coronary ligation (dog 2). Both ventricular function curves were noted to be linear before and after right coronary ligation as determined by linear regression analysis. The right ventricular function curve was markedly shifted down to the right. It was also rotated in a clockwise direction. LVEDP = left ventricular end-diastolic pressure; LVSWI = left ventricular stroke work index; RVEDP = right ventricular end-diastolic pressure; RVSWI = right ventricular stroke work index.

intervention periods. Ventricular end-diastolic pressure-stroke work index relations and the relations between LV and RV end-diastolic pressure were fitted to linear or exponential regression lines ($y = a \cdot x + b$ or $y = a \cdot b^x + c$) using the least-squares methods. Increases in stroke work indexes between given end-diastolic pressures were calculated by these regression lines and their means and standard deviations were used for statistical analysis. Hemodynamic changes with each intervention were analyzed by a paired t test of $n - 2$ degrees of freedom. An unpaired t test of $n - 1$ degree of freedom was performed for comparison of 2 groups.

Results

Hemodynamic study: *Right coronary ligation:* Representative tracings from dog 1 are shown in Figure 1. Right coronary ligation increased the mean value of RV end-diastolic pressure by 1.5 mm Hg, while RV systolic pressure was decreased. The LV stroke work index was reduced, but its percent reduction was less than that in the right-ventricle ($p < 0.01$). LV peak dP/dt did not change (Table I). In each dog, RV and LV function curves were constructed. Right coronary ligation shifted the RV function curve down more than that in the left ventricle to the right (Fig. 2) (dog 2). The increases in stroke work index decreased only in the right ventricle (Table I). The relationship between LV and RV end-diastolic pressure was linear before and after ligation (Fig. 3) (dog 3). Their slopes increased, although their intercepts did not change. (Table I). In the 2 dogs, the RV stroke work index was reduced 50% in the resting state; they died with acute hemodynamic deterioration when preload to the right ventricle was decreased after volume loading.

Septal branch of the left coronary artery ligation: Septal branch ligation increased the mean value of RV and LV end-diastolic pressures with decreases in RV and LV stroke work index to the same extent (Table II). The reduction in the RV stroke work index induced by septal branch ligation was less than that induced by right coronary ligation ($p < 0.05$). After septal branch ligation, not only the RV but also the LV function curves shifted to the right; however, both remained linear. Changes in increases of the stroke work indexes in response to volume loading were reduced only in the right ventricle (Table II). The relationship between LV and RV end-diastolic pressures was linear before and after septal branch ligation. Their slopes and intercepts were not changed (Table II). One dog (dog 9) died with hypotension due to fatal arrhythmia during preload reduction to the right ventricle after volume loading.

Combined right coronary and septal branch ligation: In the 12 dogs with right coronary or septal branch ligation, the contralateral coronary artery was occluded after resetting of RV end-diastolic pressure at 4 mm Hg. Two dogs died with fatal arrhythmias. Two others (dogs 6 and 7) in which the RV stroke work index had already been reduced >50% after right coronary ligation died with hemodynamic deterioration after additional septal branch ligation. In 1 of these 2 (dog 7), RV end-diastolic pressure increased up to 12 mm Hg with decrease in RV systolic pressure and cardiac output, although LV end-diastolic pressure stayed within normal range (Fig. 4).

In the 8 dogs that survived combined coronary ligation, the mean value of RV end-diastolic pressure increased 1.9 mm Hg. The RV stroke work index was reduced by 55% with a decrease in the mean value of RV systolic pressure. Combined ligation increased LV end-diastolic pressure, although its increase was less than that in the right ventricle and it remained within

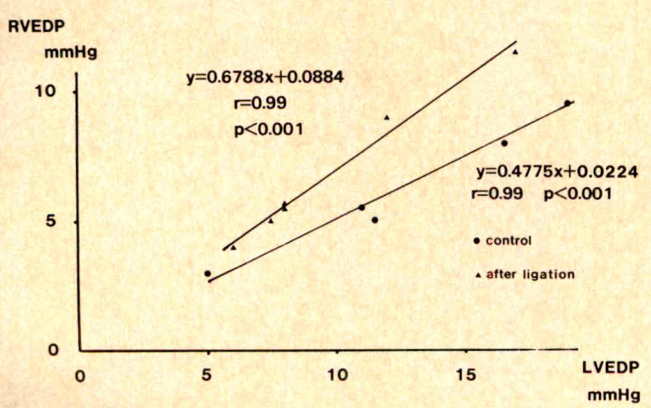

FIGURE 3. Changes in the relationship between left and right ventricular end-diastolic pressure after right coronary ligation (dog 3). The relation between left and right ventricular end-diastolic pressure was linear before and after right coronary ligation. The regression line shifted up and its slope became steeper after right coronary ligation. Abbreviations as in Figure 2.

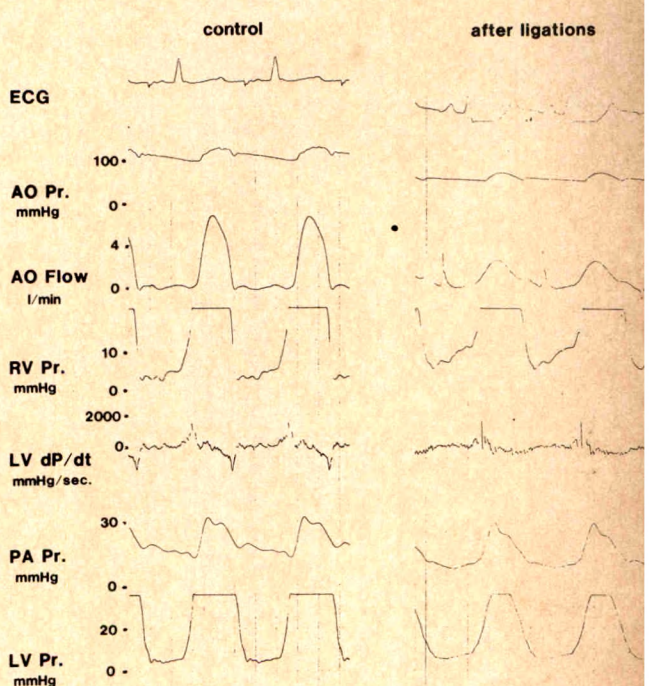

FIGURE 4. Hemodynamic changes in the right and left ventricles after combined right coronary and septal branch of the left coronary artery ligation (dog 7). Right ventricular end-diastolic pressure increased disproportionately compared with left ventricular end-diastolic pressure, which means predominant right ventricular failure. Abbreviations as in Figure 1.

both ventricles and 48 ± 4% of the right ventricle. The right coronary artery perfused 77 ± 7% of the RV free wall and 41 ± 4% of the right ventricle by weight. The right coronary artery did not perfuse the LV free wall. The septal branch supplied blood to 76 ± 11% of the VS and 37 ± 3% of the right ventricle by weight. The perfusion area of the septal branch was 26 ± 2% of the left ventricle (LV free wall + VS), but showed no perfusion area in the LV free wall or in the RV free wall. There was no difference between the perfusion area of the right coronary artery and that of the septal branch in the right ventricle.

Discussion

Clinical RV infarction can be recognized by disproportionately high RV end-diastolic pressure compared with LV end-diastolic pressure with or without a restrictive pressure pattern of the right ventricle.[4,9–14] In almost all the cases of RV infarction, the RV free wall and the posterior one third of the VS have been involved.[7] On the other hand, it has been reported that RV failure could not be produced in animal experiments in which the RV free wall only had been destroyed with the opened parietal pericardium.[1–3] These clinical and experimental observations suggest that contraction of the VS plays a role in RV pump function, and the parietal pericardium modifies RV performance.

In the present experiment, ischemia in RV free wall with the pericardium intact decreased the RV stroke work index >40%. These data are consistent with those of Goldstein et al.[15] They reported that the damage to the RV free wall reduced not only the RV stroke work index, but also that in the left ventricle by >60%. In their experiment, RV end-diastolic pressure was in the upper normal range initially, which may mean preexisting high preload to the right ventricle. Fixler et al[16] reported that the RV function curve during acute volume loading depressed after right coronary ligation which reduced RV myocardial blood flow by 40%, while that of the left ventricle did not shift. The shift of the function curve to the right and the reduction in the increase of the RV stroke work index to volume loading after right coronary ligation in our study are consistent with those in previous reports.

There have been a few reports that elevation of the filling pressure of 1 ventricle changed the pressure-volume relation and the function curve in the contralateral ventricle. The overloading of the right ventricle induced distortion of LV geometry and disturbed its filling under a given LV filling pressure. The existence of the intact pericardium enhanced these interactions.[17–21] In our study, the rightward shift of the LV function curve without any decrease in LV peak dP/dt and increase in LV stroke work index after right coronary ligation was observed. It does not mean real LV dysfunction and is mainly due to direct interaction from the damaged right ventricle. The upward shift in the LV and RV end-diastolic pressure relation suggested that the compliance of the right ventricle may be reduced more than that of the left ventricle and that pressure-volume relations in both ventricles may be altered by direct interaction between them.

There have been few reports on the role of the VS in RV function. Brooks et al[22] studied the effects of ischemia of the anterolateral, anteroseptal, or inferoseptal wall of the left ventricle on both ventricular functions in pigs, whose coronary system is similar to that of human beings. RV function was depressed only by the inferoseptal and anteroseptal ischemia. This finding suggests that the contraction of the VS makes some contribution to maintaining RV function. Fixler et al[16] produced selective ischemia in the VS in dogs by septal branch ligation, which reduced its blood flow >40% and reported that RV function was depressed without any depression of LV function. The fact that LV peak dP/dt was decreased in our study could be evidence of an LV contraction abnormality induced by septal branch ligation. No significant change in LV and RV end-diastolic pressure relation suggested that the compliance of each ventricle was affected to the same extent.

It has not been previously reported that the VS and RV free wall were destroyed at the same time and that predominant RV failure could be produced experimentally. We were able to produce predominant RV failure with combined right coronary and septal branch ligation, demonstrating the contribution of contraction of the RV free wall and VS to RV function (Fig. 4).

Santamore et al[23] reported that RV pressure development might depend mainly on the contraction of the left ventricle, although Goldstein et al[15] stated the importance of the RV free wall. In our study, RV systolic pressure was decreased moderately after the destruction of the RV free wall, the VS, or both. It can be stated that their contraction plays an important role in ejection of blood from the right ventricle but not so much in the development of RV pressure.

Clinical or hemodynamic signs of RV infarction have been reported to improve or disappear within several days after onset.[9–11] The left ventricle dilates to compensate for the decreased ejection fraction and improves stroke volume. The existence of the same mechanism in the damaged right ventricle has already been suggested in clinical reports.[24,25] We can presume that the pressure pattern in RV infarction is caused by the restrictive effect of the pericardium on the dilating right ventricle. It was suggested that the right ventricle dilated after the destruction of the RV free wall, although the left ventricle might be distorted and its volume might be decreased, even at the same filling pressure with the pericardium intact.[15] Hemodynamic improvement in RV performance after pericardiotomy supports the existence of such a restrictive mechanism.

It has been said that volume loading is effective for the low output state found in clinical RV infarction. The present study suggests that in clinical RV infarction, not only volume expansion but also pericardiotomy improves such a decrease in cardiac output without worsening of pulmonary congestion, even in cases with combined LV dysfunction, although the latter might not be practical in the acute stage of RV infarction. It is presumed that pericardial distension after the acute stage may cause hemodynamic improvement and disappearance of a restrictive pressure pattern in the right ventricle in clinical situations.

Effect of Fluocarbon Exchange Transfusion on Myocardial Infarction Size in Dogs

GRAHAM R. NUNN, MD, GARLAND DANCE, BA, JENNIFER PETERS, and LAWRENCE H. COHN, MD

Fluosol DA (20%), a perfluocarbon with high oxygen solubility, was administered by concurrent exchange transfusion (30 ml/kg) to anesthetized open-chested adult greyhounds (n = 9) 1 hour after left anterior descending coronary ligation. Mechanical ventilation using 100% oxygen was used throughout the experiment. A second similar group (n = 9) received 0.9% normal saline solution (30 ml/kg), and a third group (n = 9) received no further intervention. Systemic, right atrial, and left atrial pressures were not altered by the exchange transfusion. Monastryl blue dye was injected through the left atrial line at 6 hours after ligation to define the area of myocardium at risk (A_R); the animals were then killed and the heart was excised. The left ventricle was sliced at 5 mm intervals and stained using triphenyltetrazolium chloride, defining areas of necrosis (A_N). The ratio of A_N/A_R and total left ventricular mass were then compared with the use of planimetry.

The results were as follows: the A_N/A_R ratio in the 9 control animals was 90 ± 2 (mean ± standard error of the mean); in the 9 animals who received saline solution it was 88 ± 2; and in the animals who received Fluosol it was 67 ± 4 ($p < 0.01$ compared with control; $p < 0.001$ compared with the saline group).

Fluocarbon exchange transfusion may reduce infarct size when administered after coronary occlusion.

After coronary occlusion, the total mass of myocardium infarcted is an important determinant of morbidity and mortality.[1–3] The extent of myocardial necrosis is not necessarily predetermined at the time of coronary occlusion, but rather a central area of inevitably necrotic tissue is surrounded by a zone of threatened but potentially salvageable ischemic myocardium.[4–7] Several agents have been shown to be beneficial in reducing the ultimate area of myocardial infarction (AMI) when applied during the period of myocardial ischemia.[8–12] The role of oxygen therapy in the management of AMI has been well explored,[13–15] and fluocarbons with extremely high oxygen solubility have been shown to act as effective agents of oxygen transport.[16–20] There has been speculation that these agents may provide beneficial effects to ischemic myocardium because their small particle size allows penetration of edematous vessels occurring as part of the "no reflow" phenomena,[21] and because of their ability to carry oxygen in physical solution, to release oxygen to tissues at low tissue partial pressure of oxygen[22] and their ability to transport carbon dioxide away from ischemic, acidotic tissues functioning under conditions of anaerobic metabolism.

This study was designed to evaluate the effect of Fluosol DA (20%) on the area of AMI, given as a partial exchange transfusion 1 hour after acute coronary occlusion in the dog and evaluated 6 hours after onset of ischemia.

Methods

Adult retired racing greyhounds, weighing 22 to 32 kg (mean 26.5) were anesthetized with sodium thiopental (30 mg/kg intravenously); anesthesia was maintained using chloralose-urethane (6.67 g of chloralose and 80 mg of urethane in 500 ml of 0.9% normal saline solution) given in divided doses of 0.5 ml/kg as required.

All animals were intubated and ventilated with 100% oxygen using a model 607 Harvard respirator, semiclosed circuit,

A_N = area of necrosis; A_R = area at risk.
Values given are mean percent ± standard error of the mean. Numbers in parentheses represent the range for each group.

and in-line carbon dioxide absorption. Femoral arterial and venous lines were established and median sternotomy was performed. Systemic arterial and left arterial pressures (through a left atrial appendage catheter) were continuously monitored, together with electrocardiogram, temperature (esophageal), arterial blood gases, and right arterial pressures. Animals were pretreated with procainamide, 500 to 700 mg (20 mg/kg intravenously), 20 minutes before left anterior descending (LAD) coronary artery ligation and thereafter at a rate of 100 mg hourly. In addition, xylocaine (100 mg intravenously and 100 mg topically to the heart) was given at the time of occlusion and subsequently as arrhythmias occurred.

The LAD artery was isolated and snared using a silicone elastomer tape approximately at its midpoint, the actual position being determined by the size and distribution of its diagonal branches. Occlusion at this point produced an area of ischemia of 10 to 25% of the left ventricular mass. The occlusion of the LAD artery was maintained for 6 hours at which time monastryl blue dye (Dupont B.W. 372-P Phthalo-Blue B) was injected into the left atrium and distributed to the nonischemic myocardium at physiologic pressures. The dogs were then killed and the heart quickly excised and sectioned. The left ventricle was isolated from the atria and right ventricles and then cross-sectioned at 5 mm intervals. The left ventricular slices were incubated in triphenyltetrazolium chloride (TTC) for 7 minutes at 35°C. The slices were then placed between 2 glass plates and tracings were made on celluloid sheets. The viable myocardium within the non–monastryl-blue-stained area at risk could be determined by the red stain imparted by TTC in the presence of lactate dehydrogenase. Thus, an area of necrosis (A_N), an area at risk (A_R), and the total left ventricular area for each slice could be defined by planimetry. The ratios of A_N/A_R and A_R to left ventricular mass (A_R/total) were then calculated and compared.

Study groups: Three groups, each with 9 animals, were randomly assembled using 1 of 3 protocols. In Group I, 6-hour ligation of the LAD artery was done without further intervention apart from the maintenance of normal body temperature (Multi-Heat 81 type WP automatic electric heating pad), pH, partial pressure of carbon dioxide (IL Instrumentation Lab Micro 13), and the treatment of arrhythmias. In Group II, a 30 ml/kg 0.9% normal saline solution exchange transfusion was begun; 1 hour after LAD artery ligation the exchange was done in 100 ml aliquots from the central venous line. By this method, there was no change in left atrial or systemic pressure. Group III received Fluosol DA (20%) 1 hour after LAD artery ligation by a similar method of exchange (30 ml/kg). All animals were followed for 6 hours and killed, and the hearts were treated as described previously.

Results

The results are summarized in Tables I and II. There was high arterial partial pressure of oxygen in all 3 groups, and this was maintained throughout the procedures. Arterial blood gases and hematocrit before and after exchange transfusion are shown in Table I. No significant alteration occurred in any of these measurements except the hematocrit level in the exchange groups. There were no significant changes in systemic arterial and left ventricular filling pressures before and after exchange at death in all experimental groups.

Table II shows the ratios of A_N/A_R and A_R/total left ventricle. The mean area at risk was 24, 18, and 22% in the 3 respective groups (difference not significant). The A_N/A_R ratio was significantly different in the Fluosol exchange group compared with the control group ($p < 0.01$) and saline solution exchange ($p < 0.001$).

Discussion

The results of this study demonstrated that the administration of Fluosol DA (20%) 1 hour after the acute coronary occlusion significantly decreased the AMI seen at 6 hours when compared with similarly managed but untreated control dogs, or with saline exchange transfusion. These findings are in accordance with those of Glogar et al,[3] who administered 40 ml/kg of fluocarbon and evaluated the A_R by autoradiography in a pretreatment model. They differ, however, from our experiment in that ours is a clinical treatment model of AMI with therapy begun after the event, whereas in their experiment the exchange transfusion with Fluosol was performed before ligation of the LAD artery. Although the mechanism of Fluosol DA (20%) protection was not elicited in this experiment, it is postulated that the protection of the heart was by high arterial oxygen saturation in and around the ischemic area. Fluocarbons may increase oxygen delivery to ischemic myocardium because their oxygen-carrying capacity at high partial pressure of oxygen is actually superior to blood oxygen (39.4 ml/100 ml of Fluosol versus 20 ml of oxygen/100 ml of blood).[23] The decreased viscosity or small size particles (<0.1 μm) of Fluosol probably improves distribution of oxygen to the myocardium at risk. Rude et al[24] documented increased delivery of oxygen by Fluosol DA to ischemic myocardium by measuring increases in intramyocardial partial pressure of oxygen with a mass

spectrophotometer. This increase was shown with fluocarbon with a mass spectrophotometer. This increase was shown with fluocarbon but not with oxygen alone.[24] We believe that hemodilution per se is not responsible since moderate saline hemodilution did not alter A_N/A_R over controls with normal hematocrit, and previous work has shown no added benefit of hemodilution to infarct size reduction.[25,26]

In this study, an animal model was used that simulated the clinical findings of acute myocardial ischemia progressing to necrosis. The techniques of defining A_R and A_N have previously been shown to be reliable methods of defining areas in which regional myocardial blood flow is <0.4 ml/min/g of tissue and correlate with microscopic and electron microscopic analyses of necrotic tissue and other methods of defining area of risk, such as autoradiography.[23,27,28] The TTC vital staining technique has been well validated both clinically and experimentally as a marker of necrosis as early as 4 hours after occlusion.[28–30]

Myocardial necrosis is a time-related process, and interventions such as Fluosol DA administration that may modify this sequence and result in reduced necrosis within the ischemic area may have important implications in clinical practice in the treatment of acute myocardial infarction.

EDITORIAL

Fibronectin: Cardiovascular Aspects of a Ubiquitous Glycoprotein

MARC K. EFFRON MD and DONALD C. HARRISON, MD

Our concepts of cardiovascular physiology and disease are largely founded on macroscopic observations of the mechanical and structural state of the heart and vessels. This knowledge is augmented by recent studies of cellular receptors, electrophysiologic features, contractile proteins, and myocardial metabolism. At the level of cellular function, the cardiovascular system remains relatively unexplored. Interactions between cells may determine the morphogenesis and homeostasis of tissue, as well as the response of tissue to increased functional demand or injury. In this editorial, we focus upon the actions of fibronectin, an extracellular glycoprotein, in modulating cellular interactions in the cardiovascular system. We present several potential roles for fibronectin in cardiovascular function and dysfunction which, although lacking immediate therapeutic implications, prompt the interest and speculation of the cardiologist.

Fibronectin is a major cell surface glycoprotein distributed widely in the extracellular matrix of mesenchymal tissues and present in soluble form in the plasma.[1–4] It has been shown to facilitate a vast array of cell processes, including formation of intercellular contacts, adhesion and spreading of cells on substrata, and mediation of cell differentiation and tissue morphogenesis. The tissue distribution and the molecular and cellular actions of fibronectin are applicable to the embryogenesis of the heart and vasculature, the physiology of the blood vessel, and mechanisms of arteriosclerosis. thrombus organization, and myocardial healing after infarction.

Molecular Structure

Plasma and tissue fibronectins have only minor biochemical[5] differences. The basic 220,000 dalton molecular weight subunit occurs most commonly in dimer form in the plasma[6] and also as higher molecular weight disulfide-linked polymers when associated with cells[7] (Fig. 1). Fibronectin is comprised of approximately 5% carbohydrate, which may serve to resist proteolysis of the macromolecule.[8] Intrachain disulfide bonds occur in the polypeptide portion of the molecule. Free sulfhydryl groups are also present and appear to be required for binding of fibronectin to the cell surface.[9]

Tissue and Cellular Distribution

Immunofluorescent studies with antifibronectin antibody have delineated the tissue and cellular distribution of fibronectin. As a major component of the extracellular matrix, fibronectin is extensively distributed in fibrillar form in basement membranes of vessels and capillaries, around smooth muscle cells, at the sarcolemma of striated muscle, and in loose connective tissue.[10,11] It is topographically associated with elastic fibers in the internal and external elastic lamina of large vessels.[12] Complete studies of the distribution of fibronectin in the heart have not been performed. Fibronectin is synthesized in vitro by several cell types, including fibroblasts,[13] endothelial cells,[14] smooth muscle cells,[15] and myoblasts.[16] In tissue culture, fibronectin appears as a fibrillar network between cells and the substratum, between cells at points of intercellular contact, and on the apical cell surface. This distribution varies with cell type, culture conditions, and stage of differentiation and growth.

Cardiovascular Morphogenesis

The ability of fibronectin to induce cell migration and intercellular contact in vitro implies a possible role during embryogenesis. In the chick embryo area vasculosa, fibronectin is concentrated under the epiblast at the leading edge of migrating vascular mesenchyme.[17] Myoblasts require fibronectin for attachment and elongation upon a gelatin-coated substrate and align themselves along oriented fibrils and streaks of fibronectin.[18] Observations of chick embryo heart tissue in organ culture suggest that fibronectin dominates the associative behavior of ventricular tissue.[19] Apposition of 2 dissimilar tissues in organ culture consistently leads to spreading of 1 tissue type over the other. When ventricular myocyte aggregates of different ages are apposed, the aggregate segregating to an internal position displays more surface fibronectin than the aggregate that spreads to an external position. In fetal rat hearts,

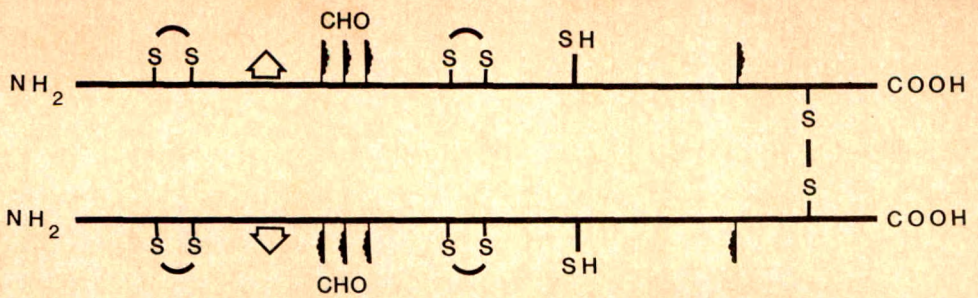

FIGURE 1. Simplified structural model of fibronectin in dimer form. Two polypeptide chains are joined near the carboxy-terminal ends. Inter- and intrachain disulfide bridges (S-S), free sulfhydryl groups (SH), carbohydrate residues (CHO), and the binding sites for collagen and fibrin (**open arrows**) are depicted. (Adapted from Hayashi and Yamada[5] and Wagner and Hynes.[9])

immunofluorescent localization of fibronectin is particularly prominent at the crest of the developing interventricular septum.[20] Thus, fibronectin is present in the developing heart, probably is synthesized by cardiac mesenchyme, and may contribute to formation of the important septal region and other facets of cardiac and vascular structure.

Endothelium and Subendothelium

Endothelial cells provide a selective barrier and a site of active transport between the blood and tissues and maintain this vascular interface by the repair processes of cell proliferation and migration.[21] Fibronectin synthesized by cultured endothelial cells is laid down as a dense fibrillar network beneath the cell monolayer. With disruption of the endothelial lining of the blood vessel, fibronectin in the subendothelial matrix may contribute to adhesion of blood elements[22] and thrombogenesis.[23] Fibronectin may also facilitate migration of endothelial cells for repair of vessel injury and neovascularization. Certain endothelial cells identified in culture secrete fibronectin as they migrate, leaving a continuous trail of the glycoprotein.[24] When these migratory endothelial cells and previously stationary cells are combined in culture, the previously sedentary cells closely follow the path of the migrating cells. Fibronectin may thus serve as a transducer of signals for endothelial cell movement.

As a selective barrier, the endothelium must mediate translocation of leukocytes across the vessel wall. Adherence of granulocytes to the endothelium in vivo precedes their entry into tissue. Recent investigations with radioiodinated plasma fibronectin indicate that monolayer endothelial cells bind large numbers of exogenous fibronectin molecules with strong avidity.[25] Immunofluorescent studies reveal an initial diffuse distribution of exogenous fibronectin on the surface of endothelial cells followed by delayed apical aggregation of the glycoprotein. This surface modulation correlates with the ability of fibronectin to facilitate adhesion of polymorphonuclear granulocytes to the endothelial monolayer.[26]

Atherosclerosis

The strategic location of fibronectin in the arterial wall and its involvement in cell interactions and migration suggest a role in the pathogenesis of atherosclerosis. This possibility has been studied by Stenman et al,[27] who have observed prominent immunofluorescent staining for fibronectin in early cellular atherosclerotic lesions of human muscular arteries.[27] In advanced sclerotic plaques, diffuse staining for fibronectin remains but is less intense. Arterial injury has been proposed as the common precursor of intimal plaque formation.[28] At sites of injury, fibronectin may provide an extracellular matrix which directs cellular invasion either for appropriate tissue repair or for the accumulation of smooth muscle cells and other elements culminating in the atherosclerotic plaque.

Thrombus Organization and Myocardial Healing After Infarction

A significant quantity of fibronectin becomes incorporated into fresh thrombus, as the serum concentration is 20 to 50% less than the plasma concentration.[29] Fibronectin binds to fibrin during clot formation and becomes covalently cross-linked to fibrin. Cross-linking of fibronectin to fibrin on a fibrin-coated substratum enhances the attachment and spreading of fibroblasts.[30] Thus, although fibronectin is not required for clot formation, its presence within thrombi may mediate the influx of cells and thrombus organization.

Fibronectin has a similar affinity for collagen, which is reflected in the codistribution of fibronectin and collagen in the connective tissue extracellular matrix.[31] Covalent cross-linking of fibronectin to collagen is also observed.[32] In active granulation tissue, fibronectin appears early with invading fibroblasts before the appearance of collagenous proteins.[33] Type III collagen is formed subsequently, and when the collagen organizes into bundles, the fibronectin content is greatly reduced.

Repair of myocardium after infarction may depend, in part, on the cell translocation and tissue organizing properties of fibronectin. Pathologic stages of infarct healing include early exudation of leukocytes with dense infiltration of the damaged myocardial segment, removal of necrotic muscle fibers, and later scar formation with fibroblast activity and progressive maturation of collagen bundles. The cellular and molecular interactions of fibronectin observed in vitro are applicable to these processes of tissue repair.

Conclusions

The ubiquity of fibronectin as a major extracellular and cell surface glycoprotein has inspired investigators in various biological disciplines to study the physiologic and pathophysiologic features of this macromolecule. Our understanding of fibronectin is at an early stage, yet permits these several correlations with cardiovascular structure and function. Fibronectin can generally be regarded as a mediator of cellular contact and behavior, and perhaps its panoply of actions may ultimately be clinically important for patients with cardiovascular disorders. Disturbance of fibronectin distribution or metabolism has not been demonstrated as a primary cause of disease states. The complete in vivo role of fibronectin in the cardiovascular system awaits further exploration.

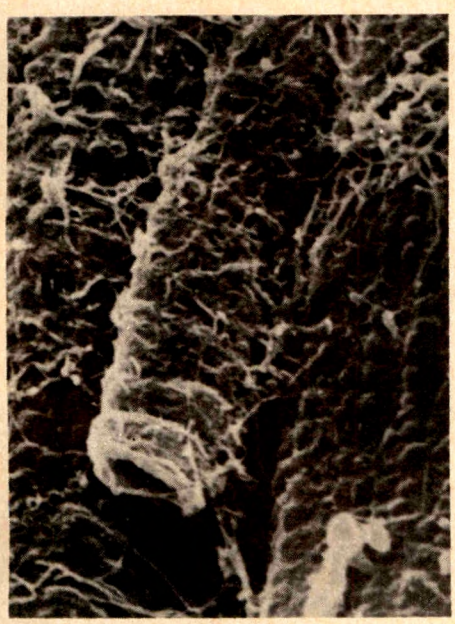
Coronary Artery Spasm and Thrombosis

Volume 14/Number 1
Cardiovascular Clinics



The Editor-in-Chief of the Cardiovascular Clinics is Albert N. Brest, MD.

Research on the causes of angina and myocardial infarction has resulted in many important discoveries during the last ten years. Current knowledge shows that such intracoronary events as coronary artery spasm and thrombosis are among the major contributing factors to coronary artery disease.

In **Coronary Artery Spasm and Thrombosis** the interrelated roles and clinical importance of these conditions are thoroughly examined. Dr. Sheldon Goldberg and the 27 contributors share their expertise in areas of diagnostic analysis, provocative testing, and treatment methods. As with all the titles in the **Cardiovascular Clinics,** this newest clinical masterwork reports on today's *most current* research studies. Order your copy now! This information is too important to be without.

Guest Editor: **Sheldon Goldberg,** MD, Associate Professor of Medicine, Jefferson Medical College; Director, Cardiac Catheterization Laboratory, Thomas Jefferson University Hospital, Philadelphia, PA.; with 27 other contributors. 224 pp. Illustd. August 1983. $40.00.

Contents: Coronary Artery Spasm: Historic Aspects. Coronary Thrombosis: Historic Aspects. The Normal Regulation of Coronary Blood Flow. Pathophysiology of Angina Pectoris Due to Coronary Artery Spasm. Interactions of the Arterial Wall, Plaque, and Platelets in Myocardial Ischemia and Infarction. The Role of Coronary Artery Spasm in Acute Myocardial Infarction. The Clinical Syndrome of Variant Angina. The Role of Coronary Artery Spasm in Unstable Angina Pectoris. The Role of Coronary Artery Spasm in Exercise-Induced Angina. Value and Limitations of Provocative Testing to Assess the Efficacy of Treatment in Variant Angina. Provocative Testing for Coronary Artery Spasm: Specific Methodology. Postoperative Coronary Vasospasm. Clinical Pharmacology of Calcium Entry Blockers. Treatment of Vasospastic Angina. Role of Platelet-Active Drugs in Coronary Artery Disease. Acute Myocardial Infarction—Coronary Thrombosis and Salvage of the Ischemic Myocardium. Reduction of Infarct Size with Thrombolytic Agents.

Vital new books for the clinician...

NONINVASIVE DIAGNOSTIC METHODS IN CARDIOLOGY

Volume 13/Number 3
Cardiovascular Clinics

Methods for noninvasive diagnosis and testing for virtually every form of cardiac dysfunction are explained. Nuclear medicine, echocardiography, computerized scanning and positron tomography are but a few of the broad range of methods directly applicable to the problems you encounter in daily practice. Guest Editor: **Noble O. Fowler,** MD, Professor of Medicine and Director, Division of Cardiology, University of Cincinnati, Ohio; with 45 contributors. 410 pp. Illustd. Ready July 1983. $50.00.

A GUIDE TO CARDIAC PACEMAKERS

All the information you so vitally need, concerning the profusion of pacemakers currently available, can be found in this single, well illustrated source. All major topics are covered in-depth, including pacemaker function and variations, manufacturers and their models, plus an important section illustrating the radiologic identification of pacemaker models within the living patient. Edited by **Dryden Morse,** MD; **Robert M. Steiner,** MD, and **Victor Parsonnet,** MD. About 545 pp., 400 ill. Ready September.1983. $90.00.

I would like to receive the indicated books on 30-day approval.

EXERCISE in Cardiovascular Health and Disease

Edited by
Ezra A. Amsterdam, MD, Chief Coronary Care Unit, Univ. of Calif. School of Medicine
Jack H. Wilmore, PhD, Professor and Head Dept. of Physical Education & Athletics, Univ. Arizona
Anthony N. DeMaria, MD, Dir. Echocardiography Section, Univ. of Calif. School of Medicine

SEPTEMBER 1977, 408 PAGES, ILLUS.

This comprehensive work covers every aspect of exercise and its role in Diagnosis, Treatment, and Prevention of cardiac disease.

The scope of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE is so broad that it goes from something as basic as a detailed study of the heart muscle itself to the latest advances in cardiac rehabilitation.

Special attention is given to such subjects as:

- ☐ Present status of exercise testing and training in terms of physiological bases and clinical applications
- ☐ Nuclear cardiology
- ☐ Computer analysis of the exercise ECG
- ☐ Stress myocardial scintigraphy
- ☐ Various interpretations of exercise tests in the asymptomatic population

The editors have brought together a distinguished group of specialists—all of whom have made major contributions to the field. Included are outstanding scientists, clinicians, exercise physiologists, and physical educators.

For you who have any interest—professional or personal—in exercise and the heart, we urge you to *look* at a copy of EXERCISE IN CARDIOVASCULAR HEALTH AND DISEASE. That's right! You're invited to *look* it over before buying it.

Send for your copy of Exercise in Cardiovascular Health and Disease today. *Then use it for 30 days without risk.*

Yorke Medical Books AJCG3
Box C-757, Brooklyn, New York 11205

Please send me a copy of EXERCISE in Cardiovascular Health and Disease for 30 days free examination and use. If I decide to keep it, your invoice will be honored ($42.50 plus shipping cost). Otherwise, the book will be returned for full refund or credit.

☐ Full payment enclosed, publisher pays shipping.
☐ Please bill me, plus cost of shipping.
☐ Charge my credit card: ☐ MasterCard ☐ Visa.

The 11th Annual Subspecialty Review Series

Cardiovascular Disease

October 10-14, 1983

THE COOK COUNTY GRADUATE SCHOOL OF MEDICINE

This five-day subspecialty review is comprehensive, current, and intensive. It will provide a detailed review of invasive and non-invasive diagnostic techniques, electrocardiography, and the physiology and pathology of coronary artery disease, valvular heart disease and other important cardiac disorders.

Although this course is primarily designed to meet the needs of candidates preparing for the Subspecialty Examination in Cardiology, it is also a rewarding experience for already-certified specialists seeking a thorough review and update of their field. Participation earns 40 AMA Category 1 credit hours. Fees: $450 for practicing physicians; $340 for residents and fellows.

For registration or further information, write or call: The Cook County Graduate School of Medicine, 707 South Wood Street, Chicago, Illinois 60612; (312) 733-2800.

The Graduate School . . . over half a century of continuing medical education.

When patients need more potassium than tablets can easily offer...

©1982 Sandoz, Inc.

Consider the simplicity of KLORVESS® EFFERVESCENT GRANULES

Each packet (2.8 g) provides 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, and L-lysine monohydrochloride 0.913 g.

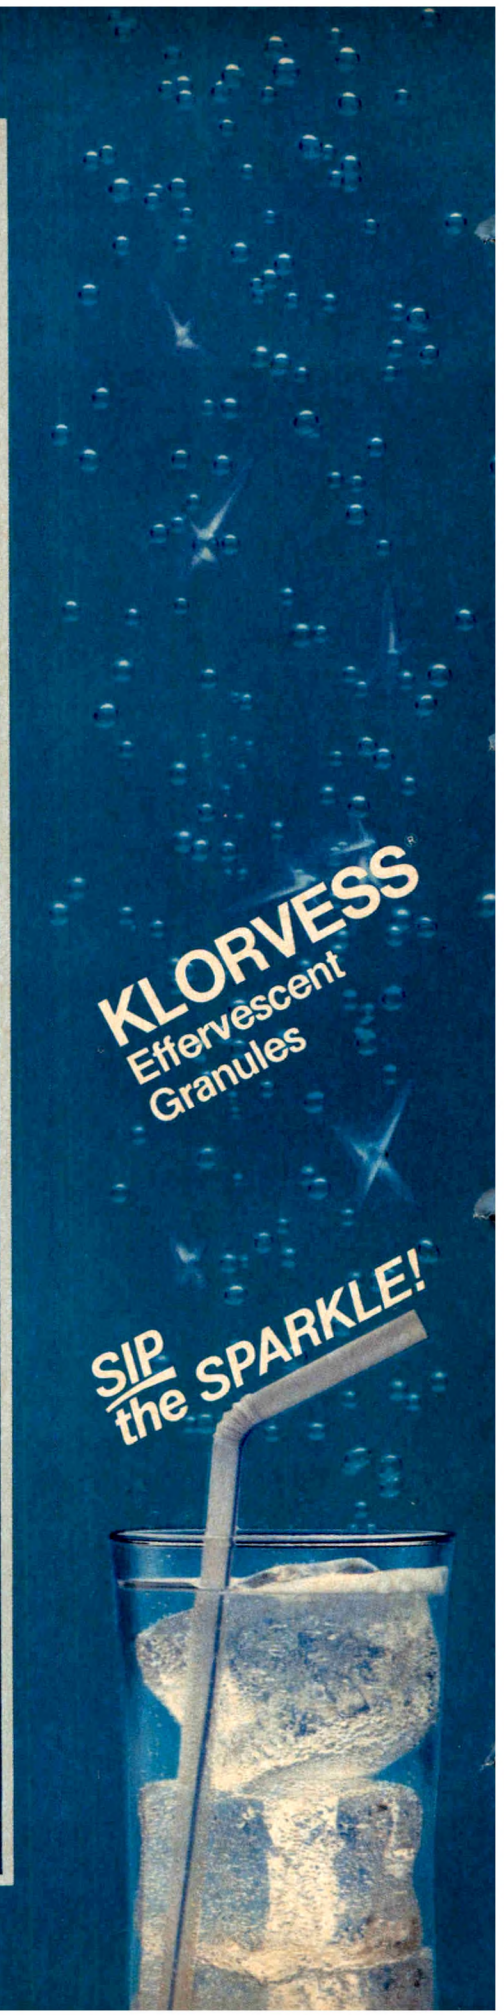
The patient on higher doses of antihypertensive medication, diuretics and/or digitalis, may need additional potassium supplementation...40 mEq/day or more. KLORVESS Effervescent Granules offer the following advantages:

- ***Each packet delivers 20 mEq of potassium***...compared with slow-release tablets that contain 10 mEq or less.
- ***Sparkling citrus flavor offers a high degree of patient compliance.*** Patients may even use KLORVESS as a "chaser" for other medications. Granules mix easily with cold water...no need for expensive juices to make palatable.
- ***Convenient effervescent granules dissolve almost immediately***...no waiting.
- ***Sugar-free, sodium-free, carbohydrate-free, dye-free formulation***...ideal for hypertensive, diabetic, or overweight patients.

PHARMACEUTICAL DIVISION
SANDOZ, INC.
E. HANOVER, NEW JERSEY 07936

Please see brief summary of prescribing information on adjoining page.

KLR-582-1



Give your patients the KLORVESS® sparkle

Klorvess® Effervescent Granules and Klorvess® (potassium chloride) 10% Liquid

Brief summary of prescribing information

DESCRIPTION: *Klorvess Effervescent Granules:* Each packet (2.8 g) contains 20 mEq each of potassium and chloride supplied by potassium chloride 1.125 g, potassium bicarbonate 0.5 g, L-lysine monohydrochloride 0.913 g in a sodium-, sugar- and carbohydrate-free effervescent formulation. Dissolution of the packet contents in water provides the potassium and chloride available for oral ingestion as potassium chloride, potassium bicarbonate, potassium citrate and L-lysine monohydrochloride.

Klorvess (potassium chloride) 10% Liquid: Each tablespoonful (15 ml) contains 20 mEq of potassium chloride (provided by potassium chloride 1.5 g) in a palatable, cherry-with-pit flavored vehicle, alcohol 1%.

INDICATIONS: For the prevention and treatment of potassium depletion and hypokalemic-hypochloremic alkalosis. Deficits of body potassium and chloride can occur as a consequence of therapy with potent diuretic agents and adrenal corticosteroids.

CONTRAINDICATIONS: Severe renal impairment characterized by azotemia or oliguria, untreated Addison's disease, Familial Periodic Paralysis, acute dehydration, heat cramps, patients receiving aldosterone-inhibiting or potassium-sparing diuretic agents, or hyperkalemia from any cause.

PRECAUTIONS: In response to a rise in the concentration of body potassium, renal excretion of the ion is increased. In the presence of normal renal function and hydration, it is difficult to produce potassium intoxication by oral potassium salt supplements. Since the extent of potassium deficiency cannot be accurately determined, it is prudent to proceed cautiously in undertaking potassium replacement. Periodic evaluations of the patient's clinical status, serum electrolytes and the EKG should be carried out when replacement therapy is undertaken. This is particularly important in patients with cardiac disease and those patients receiving digitalis. High serum concentrations of potassium may cause death through cardiac depression, arrhythmia or cardiac arrest. To minimize gastrointestinal irritation associated with potassium chloride preparations, patients should dissolve the packet contents of *Klorvess Effervescent Granules* in 3 to 4 ounces of cold water, fruit juice or other liquid or dilute each tablespoonful of *Klorvess (potassium chloride) 10% Liquid* in 3 to 4 ounces of cold water. Both of these solutions should be ingested slowly with or immediately after meals.

ADVERSE REACTIONS: Abdominal discomfort, diarrhea, nausea and vomiting may occur with the use of potassium salts. The symptoms and signs of potassium intoxication include paresthesias, heaviness, muscle weakness and flaccid paralysis of the extremities. Potassium intoxication can produce listlessness, mental confusion, a fall in blood pressure, shock, cardiac arrhythmias, heart block and cardiac arrest. The EKG picture of hyperkalemia is characterized by the early appearance of tall, peaked T waves. The R wave is decreased in amplitude and the S wave deepens; the QRS complex widens progressively. The P wave widens and decreases in amplitude until it disappears. Occasionally, an apparent elevation of the RS-T junction and a cove plane RS-T segment and T wave will be noted in AVL.

DOSAGE AND ADMINISTRATION: *Klorvess Effervescent Granules:* Adults—One packet completely dissolved 2 to 4 times daily depending upon the requirements of the patient.

Klorvess (potassium chloride) 10% Liquid: Adults—One tablespoonful (15 ml) completely diluted in cold water 2 to 4 times daily depending upon the requirements of the patient.

Both of these solutions should be ingested slowly with meals or immediately after eating.

OVERDOSAGE: Potassium intoxication may result from overdosage of potassium or from therapeutic dosage in conditions stated under "Contraindications." Hyperkalemia, when detected, must be treated immediately because lethal levels can be reached in a few hours. In digitalized patients too rapid a lowering of plasma potassium concentration can cause digitalis toxicity.

HOW SUPPLIED: *Klorvess Effervescent Granules*—packages of 30 packets (2.8 g each). *Klorvess (potassium chloride) 10% Liquid* (dark red)—as a cherry-with-pit flavored liquid in pint and gallon bottles. Klorvess Effervescent Granules and Liquid are also available in institutional packaging as follows: *Klorvess Effervescent Granules*—packages of 1000 packets; *Klorvess Liquid*—36 (3 x 12) x 4 oz Unit-of-Use bottles and 100 (4 x 25) x 15 ml Unit-Dose bottles.

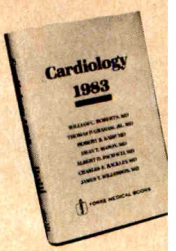
Cardiology 1983



The third issue of the New Annual providing a multidisciplinary approach to the latest, most important information on the state-of-the-art of cardiovascular medicine and surgery

What is Cardiology 1983?

- A review of the year's newest and most importa developments in cardiology
- A **multidisciplinary** approach to clinical and ap research
- A unique, cohesive summary of the state-of-the- **written**, not edited, by those making outstandin developments in the field
- A practical approach to a complicated and fast- subject designed to be read and used daily

Cardiology 1983 provides in a concise and read mat and style fundamental and new information e to understanding the current thinking on managin vascular disease. It coordinates what's new with established data, arming the reader with a perspe the field which is simply unavailable elsewhere. It use of illustrations and tables condenses valuable tion into instantly understandable knowledge.

Who are the authors?

• William C. Roberts, MD • Thomas P. Grah MD • Robert B. Karp, MD • Dean T. Mason, • Albert D. Pacifico, MD • Charles E. Rackle • James T. Willerson, MD

ISBN 0-914316-36-2 approx. 500 pp., illus., '83 $49.50 ISSN 0275-0066

First-step anginal prophyla
refined by advanced
technology

Transderm®-Nitr

nitroglycerin

A step ahead of long-acting
oral nitrates

"Transdermal delivery of nitroglycerin... overcomes the inherent problems of the oral dosage forms regarding...bioavailability, convenience and compliance."*

24-hour sustained therapeutic blood levels of nitroglycerin.
In contrast, so-called long-acting oral nitrates must be given in repeated doses throughout the day.

Eliminates the first-pass effect.
Unlike oral nitrates, which are predominantly inactivated in the liver, transdermal nitroglycerin bypasses the liver and enters directly into systemic circulation.

Only one simple application a day.
Avoids the inconvenience of multiple dosages.

Small, cosmetically acceptable and well tolerated.
Will not leak or stain clothing. May even be worn while bathing or swimming. Few reports of skin irritation.

Note: Orthostatic hypotension may indicate nitroglycerin overdosage; reduce dosage if symptoms occur. Nitrates are contraindicated in patients with increased intraocular pressure. Withdrawal should be gradual if treatment is terminated. Do not apply to distal parts of the arms and legs.

CIBA

Transderm®-Nitro

(nitroglycerin)
Transdermal Therapeutic System

DESCRIPTION
Transderm-Nitro (nitroglycerin) transdermal therapeutic system is a flat unit designed to provide controlled release of nitroglycerin through a semi-permeable membrane continuously for 24 hours following application to intact skin. Nitroglycerin (glyceryl trinitrate) is a prompt-acting vasodilator for the relief and prevention of anginal attacks. Systems are rated to release *in vivo* 2.5, 5 and 10 mg nitroglycerin over 24 hours and are in sizes of 5, 10 and 20 cm^2 respectively.

One-fifth of the total nitroglycerin in the system is delivered transdermally to the patient over 24 hours; the remainder serves as the thermodynamic energy source to release the drug and remains in the system. The rated release of drug is dependent upon the area of the system; 0.5 mg nitroglycerin is delivered *in vivo* for every cm^2 of system size.

The Transderm-Nitro system comprises four layers. Proceeding from the visible surface towards the surface attached to the skin, these layers are: 1) a tan-colored backing layer (aluminized plastic) that is impermeable to nitroglycerin; 2) a drug reservoir containing nitroglycerin adsorbed on lactose, collioidal silicon dioxide, and silicone medical fluid; 3) an ethylene/vinyl acetate copolymer membrane that is permeable to nitroglycerin; and 4) a layer of hypoallergenic silicone adhesive. Prior to use, a protective peel strip is removed from the adhesive surface.

ACTIONS
When the Transderm-Nitro system is applied to the skin, nitroglycerin is absorbed continuously through the skin into the systemic circulation. This results in active drug reaching the target organs (heart, extremities) before being inactivated by the liver. Nitroglycerin is a smooth muscle relaxant with vascular effects manifested predominantly by venous dilatation and pooling. The major beneficial effect of nitroglycerin in angina pectoris is a reduction in myocardial oxygen consumption secondary to vascular smooth muscle relaxation and consequent reduced cardiac preload and afterload. In recent years there has been an increasing recognition of a direct vasodilator effect of nitroglycerin on the coronary vessels.

In clinical studies transdermal absorption of nitroglycerin from a nitroglycerin system occurred in a continuous and well-controlled manner, for a minimum of 24 hours. Therapeutic effect can be anticipated 30 minutes after application of the system and to be maintained for 30 minutes after its removal.

INDICATIONS AND USAGE
Transderm-Nitro system is indicated for the prevention and treatment of angina pectoris due to coronary artery disease.

CONTRAINDICATIONS
Intolerance of organic nitrate drugs, marked anemia, increased intraocular pressure or increased intracranial pressure.

WARNINGS
In patients with acute myocardial infarction or congestive heart failure, Transderm-Nitro system should be used under careful clinical and/or hemodynamic monitoring.

In terminating treatment of anginal patients, both the dosage and frequency of application must be gradually reduced over a period of 4 to 6 weeks to prevent sudden withdrawal reactions, which are characteristic of all vasodilators in the nitroglycerin class.

PRECAUTIONS
Symptoms of hypotension, such as faintness, weakness or dizziness, particularly orthostatic hypotension may be due to overdosage. When these symptoms occur, the dosage should be reduced or use of the product discontinued.

Transderm-Nitro system is not intended for immediate relief of anginal attacks. For this purpose occasional use of the sublingual preparations may be necessary.

ADVERSE REACTIONS
Transient headaches are the most common side effect, especially when higher doses of the drug are used. These headaches should be treated with mild analgesics while Transderm-Nitro therapy is continued. When such headaches are unresponsive to treatment, the nitroglycerin dosage should be reduced or use of the product discontinued.

Adverse reactions reported less frequently include hypotension, increased heart rate, faintness, flushing, dizziness, nausea, vomiting, and dermatitis. These symptoms are attributable to the known pharmacologic effects of nitroglycerin, but may be symptoms of overdosage. When they persist the dose should be reduced or use of the product discontinued.

DOSAGE AND ADMINISTRATION
Therapy should be initiated with application of one Transderm-Nitro 5 system to the desired area of skin. Many patients prefer the chest; if hair is likely to interfere with system adhesion or removal, it can be clipped prior to placement of the system. Each system is designed to remain in place for 24 hours, and each successive application should be to a different skin area. Transderm-Nitro system should not be applied to the distal parts of the extremities.

The usual dosage is one Transderm-Nitro 5 system every 24 hours. Some patients, however, may require the Transderm-Nitro 10 system. If a single Transderm-Nitro 5 system fails to provide adequate clinical response, the patient should be instructed to remove it and apply either two Transderm-Nitro 5 systems or one Transderm-Nitro 10 system. More systems may be added as indicated by continued careful monitoring of clinical response. The Transderm-Nitro 2.5 system is useful principally for decreasing the dosage gradually, though it may provide adequate therapy for some patients when used alone.

The optimal dosage should be selected based upon the clinical response, side effects, and the effects of therapy upon blood pressure. The greatest attainable decrease in resting blood pressure that is not associated with clinical symptoms of hypotension especially during orthostasis indicates the optimal dosage. To decrease adverse reactions, the size and/or number of systems should be tailored to the individual patient's needs.

Do not store above 86°F (30°C).

PATIENT INSTRUCTIONS FOR APPLICATIONS
A patient leaflet is supplied with the systems.

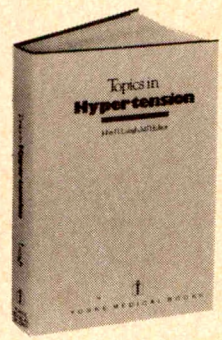
Laragh's eagerly awaited new book on the silent killer

TOPICS IN HYPERTENSION



Edited by
John H. Laragh, MD
Master Professor of Medicine
Director, The Cardiovascular Center Chief, Cardiology Division The New York Hospital-Cornell Medical Center

644 pages. 36 chapters by 85 internationally known specialists. Illustrated. Comprehensively indexed. $55.00. Available on 30-day approval.

High blood pressure is no longer only a problem of worldwide interest and relevance. It is now one in which the knowledge base has exploded to the point where the informed physician can do more and more about it in his daily practice...and can apply, to an ever-increasing extent, more sophisticated and individually tailored therapies.

Laragh's TOPICS IN HYPERTENSION places this kind of vital knowledge within instant reach of the physician. It presents a carefully selected array of discussions. It deals in depth with recent breakthroughs in understanding, diagnosing, and treating this problem.

This book is conveniently organized for effective consultation and reading:

- **Section 1** considers recently maturing biochemical and pathophysiologic aspects of the problem.
- **Section 2** deals with new physiologic approaches to diagnosis.
- **Section 3** discusses new perceptions of the clinical and prognostic aspects of hypertension.
- **Section 4** considers in detail the more recently introduced modes of therapy. These new agents presage the beginning of a new era of more selective and specific therapy for increasing numbers of patients.

The AJC in July 1958

CAROLE A. WARNES, MB, BS, MRCP, and WILLIAM C. ROBERTS, MD

During the past 25 years many symposia on various subjects have been published in the AJC. The first one was on mitral regurgitation (MR) and it appeared in the July, August, and September 1958 issues. Of the 9 articles included in this symposium, 3 appeared in the July issue and each will be discussed briefly herein.

Mitral Insufficiency: Historical and Clinical Aspects (Joseph B. Vander Veer)

This author reviews the concepts of MR which had been propagated during the previous 200 years. In the early part of the 20th century, the common view was that pure MR was exceedingly rare and probably of no clinical significance. This author considered that isolated MR was infrequent, that it was usually associated with mitral stenosis (MS) and, therefore, was of rheumatic origin. Because MR was the consequence of either rheumatic heart disease or infective endocarditis, its frequency might be expected to diminish even further with time because of the decreasing frequency of rheumatic fever and the increasing use of antibiotics. Of course, neither this author nor the others in this symposium were aware of the concepts of mitral valve prolapse or papillary muscle dysfunction—entities not described until 1963.

Clinical and Hemodynamic Observations in Pure Mitral Insufficiency (John Ross, Jr., Eugene Braunwald, and Andrew G. Morrow)

This is a classic study in many ways. Although it was considered infrequent, pure MR was described in 23 patients. This article is the first to focus on hemodynamic data in patients with "pure" MR. All 23 patients had left atrial pressures recorded (by transbronchial technique), 14 had left ventricular and mean pulmonary capillary wedge pressures recorded, and 7 had pulmonary capillary V wave pressures recorded.

Although this article is the first to describe left-sided cardiac pressures in a relatively large group of patients with "pure" MR, the absence of left ventricular pressures in 9 of the 23 patients prevents exclusion of associated MS in them. Thus, only 14 of the 23 may be considered to have had pure MR. Additionally, left ventricular angiography was not available at the time, and the effect of inspiration on the precordial systolic blowing murmur was not commented upon. The authors found that analysis of the left atrial pressure tracing was of considerably greater diagnostic value than analysis of the pulmonary capillary wedge pressure tracing, an interesting observation in view of the present-day use of the pulmonary wedge recording and the rare acquisition of left atrial pressures. This article disclosed a wide range of pressures in the left atrium, particularly of the V wave, and the explanation for this wide variation did not come until the concept of *acute* and *chronic* MR were presented several years later by some of the same authors.[1,2]

Hemodynamic Methods for Differentiation of Mitral Stenosis and Regurgitation (Hiram W. Marshall, Edward Woodward Jr., and Earl H. Wood)

In 1958, commissurotomy (or valvotomy) was available for patients with MS associated with little or no MR, but no proven operation was available for patients with pure or predominant MR. Thus, differentiation of patients with predominant or pure MR from those with pure or predominant MS was crucial in 1958. In this 36-page article, Marshall and associates discussed the hemodynamic features of these 2 lesions. They concluded that differentiation of predominant MR from predominant MS was not possible by analysis of left atrial, left ventricular, and pulmonary capillary wedge pressure tracings, but that the additional use of indicator dilution techniques improved diagnostic accuracy.

Delayed Thrombolysis of Streptokinase-Resistant Occlusive Thrombus: Documentation by Pre- and Postmortem Coronary Angiography

Jeffrey M. Isner, MD
Marvin A. Konstam, MD
Roberta V. Fortin, BS
Mark Lefebvre, MD
Deeb N. Salem, MD

Limited angiographic data and even fewer necropsy follow-up data are available regarding the fate of streptokinase-resistant intracoronary thrombus. In the patient described herein, premortem coronary angiography disclosed occlusive intracoronary thrombus, resistant to intracoronary streptokinase. Postmortem angiography performed 12 hours after completion of attempted thrombolysis demonstrated patency of the same vessel. The findings in this patient emphasize the variable behavior of occlusive thrombus after intracoronary administration of thrombolytic agents.

A 66-year-old woman was transferred to the New England Medical Center 3 hours after the onset of chest pain associated with electrocardiographic evidence of acute myocardial infarction (AMI) (Fig. 1). Coronary angiography was begun at 11:15 P.M., 4 hours and 15 minutes after the onset of AMI. The left anterior descending (LAD) coronary artery was 100% occluded immediately distal to the first septal perforator (Fig. 2a); a convex filling defect suggested that total occlusion was due to intracoronary thrombus. At 11:35 P.M., 4.5 hours after the onset of AMI, 20,000 IU of streptokinase followed by 4,000 IU/min for a total dose of 380,000 IU of streptokinase was selectively infused through the left main coronary ostium. Repeat left coronary angiography performed every 10 to 20 minutes and on completion of the infusion demonstrated persistence of the initial angiographic picture of a totally occluded LAD. The patient was transferred to the coronary care unit in stable condition. At 5:22 A.M., approximately 8.5 hours after the onset of clinical signs of AMI and 4.5 hours after completion of intracoronary streptokinase, the patient suddenly developed electromechanical dissociation and died 90 minutes later after unsuccessful cardiopulmonary resuscitation.

Postmortem examination was begun 5 hours after death. Before fixation, a barium-sulfate mixture was selectively injected into the coronary ostia at a mean pressure of approximately 80 mm Hg. Postmortem radiographs showed that the distal LAD was patent, although the proximal LAD remained focally narrowed by 90% (Fig. 2b). A histologic section taken through this site disclosed residual nonocclusive thrombus superimposed on underlying atherosclerotic plaque (Fig. 2c).

From the Departments of Medcine (Cardiology) and Pathology, Tufts-New England Medical Center, Boston, Massachusetts. Manuscript received February 9, 1983; revised manuscript received April 11, 1983, accepted April 12, 1983.

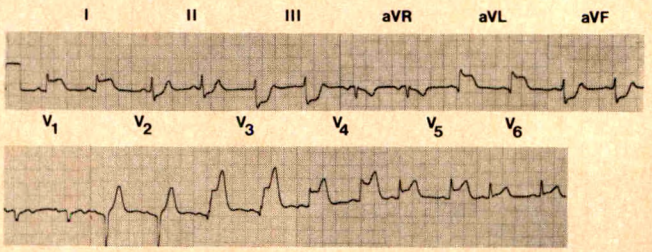

FIGURE 1. Electrocardiogram recorded shortly after admission to the emergency room demonstrates S-T segment elevation in leads I, aVL, and V_2–V_6 associated with S-T segment depression in leads II, III, and aVF; QS complexes are present in leads V_1–V_3.

Examination of the anterior left ventricular free wall of the heart revealed that it was ruptured at the site of a transmural AMI.

In 6 to 23% of patients, totally occlusive intracoronary thrombus has been reported to persist despite the administration of streptokinase after AMI.[1–4] Serial angiographic studies of such patients have been limited. Of 20 patients with total occlusion studied by Rentrop et al,[2] intracoronary thrombolysis could not be achieved in 3; repeat angiography performed 3 weeks later showed persistence of total occlusion in 1 patient, with patency of the "involved" vessel in 2. Mathey et al[3] recanalized 30 of 41 vessels totally occluded because of intracoronary thrombus; of the 11 patients in whom attempted thrombolysis was unsuccessful, 4 were restudied 7 to 21 days after AMI, and all 4 were persistently occluded. Schwarz et al[4] reported follow-up angiographic findings 4 weeks after AMI in 7 of 39 patients in whom thrombolysis was not achieved: 6 of 7 demonstrated persistent occlusion of the "involved" vessel.

Necropsy studies of patients with totally occlusive thrombus resistant to streptokinase have, to our knowledge, been limited to a single patient.[3] In this 71-year-old patient, 2 hours of intracoronary streptokinase infusion failed to reopen a totally occluded right coronary artery; necropsy performed 2 days later demonstrated persistent occlusion due to thrombus superimposed on an atherosclerotic stenosis.

The present case is unusual in that it represents 1 of the few instances in which total occlusion documented by premortem coronary angiography was evaluated by postmortem coronary angiography performed <12 hours later. Postmortem angiography documented delayed thrombolysis of an apparent streptokinase-"resistant" total occlusion during the relatively brief interval of time separating the 2 angiographic studies.

The dynamic behavior of intracoronary thrombus resistant to streptokinase illustrated in this patient has important methodologic implications for investigations designed to evaluate the role of thrombus and thrombolysis in AMI. First, failure to achieve thrombolysis acutely does not mean that thrombolysis will not ultimately occur; indeed, as demonstrated in the present

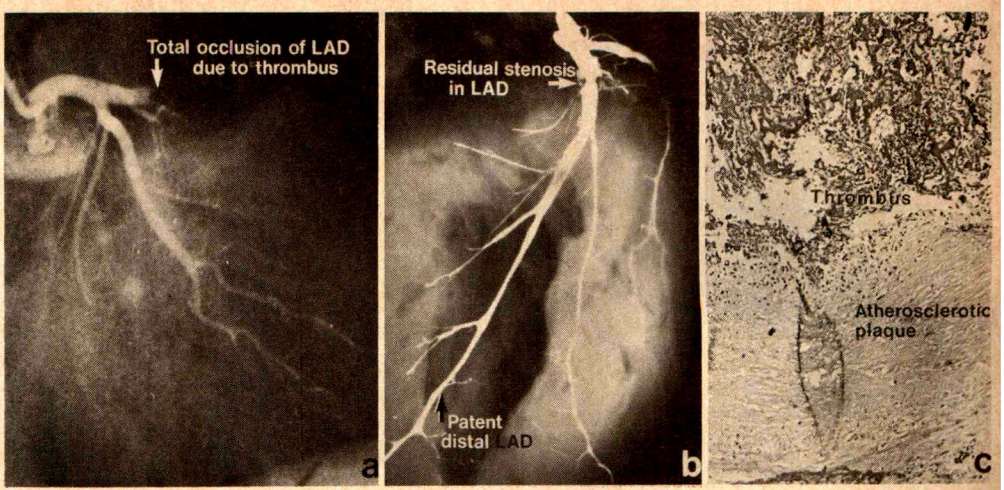

FIGURE 2. a, premortem arteriogram recorded before intracoronary infusion of streptokinase demonstrates a 100% occlusion of the left anterior descending coronary artery (LAD) immediately after the take-off of the first septal perforator. **b,** postmortem coronary arteriogram demonstrates a patent LAD with a residual proximal focal stenosis resulting in a 90% diameter narrowing. **c,** histologic section taken through the site of residual stenosis demonstrated by postmortem angiography shows a nonocclusive thrombus superimposed on underlying atherosclerotic plaque. (Hematoxylin and eosin; magnification ×20, reduced 41%.)

case, thrombolysis may occur very shortly after completion of the angiographic study. Thus, if a patient underwent thrombolysis <3 hours after the onset of AMI and the infusion were arbitrarily discontinued after 1 hour because of lack of recanalization, thrombolysis could still occur in <6 hours, a time window that might be expected to confer therapeutic benefit. Second, serial observations in the present case confirm the suggestion of DeWood et al[5] that spontaneous thrombolysis is the most likely explanation for their finding that the incidence of intracoronary thrombus decreased with increasing time after infarction. Furthermore, DeWood's patients classified as "false-positive" because the preoperative angiographic diagnosis of intracoronary thrombus was followed by failure to retrieve thrombus at the time of surgery may, in fact, have represented patients with spontaneous thrombolysis rather than a false-positive angiographic diagnosis. Third, absence of occlusive intracoronary thrombus at necropsy after AMI cannot necessarily be interpreted as evidence that no intracoronary occlusion existed during life; in fact, spontaneous thrombolysis, as demonstrated in this patient, may explain variations in the prevalence of occlusive thrombus noted in patients with AMI studied either at necropsy[6] or at angiography.

Acknowledgment: We thank Drs. Harvey Zarren, Jerry Perlow, and Daniel Wistran of Lynn, Masachusetts, who referred this patient to our catheterization laboratory.

Pulsus Alternans After Valve Replacement for Aortic Regurgitation

Nicolas L. DePace, MD
Abdulmassih S. Iskandrian, MD
A-Hamid Hakki, MD

Pulsus alternans is characterized by regular alternation of strong and weak pulses. It occurs most commonly in patients with severe left ventricular (LV) dysfunction.[1,2] Herein, we describe pulsus alternans during pacing-induced tachycardia in 2 patients after aortic valve replacement (AVR) for severe aortic regurgitation (AR).

The 2 patients were among a larger group of patients studied to evaluate LV pressure-volume relation with pacing. Both patients had isolated severe AR seen by cardiac catheterization. Both were men, aged 26 and 62 years.

The technique for combined hemodynamic and radionuclide evaluation from this laboratory has been previously described.[3] In brief, the thermodilution cardiac output, pulmonary arterial wedge pressure, and pulmonary arterial pressure were measured by a triple lumen Swan-Ganz catheter. The systemic pressure was measured by an indwelling catheter in the femoral artery. The LV ejection fraction and volume were measured by first-pass radionuclide ventriculography with a multicrystal gamma camera. Pacing was performed with a catheter in the coronary sinus and terminated in the 2 patients because of development of

From the Likoff Cardiovascular Institute of Hahnemann University and Hospital, Philadelphia, Pennsylvania. Manuscript received January 17, 1983; revised manuscript received March 31, 1983, accepted April 4, 1983.

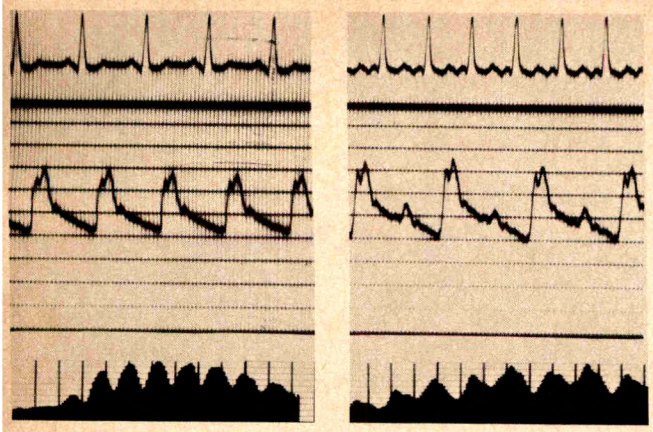

FIGURE 1. Femoral artery pressure tracings (scale 0 to 200 mm Hg) and time-activity curves in the control state (**left**) and with rapid pacing in the postoperative study in Patient 1 (**right**). The time-activity curve was obtained from the left ventricular region of interest using first-pass radionuclide ventriculography. The peaks represent end-diastoles and the troughs represent end-systoles. The difference between peaks and troughs represents the stroke volume counts in individual beats. The time-activity curve in the control state is normal, showing a gradual increase followed by a decrease in end-diastolic counts in sequential cardiac cycles as the bolus of radioactivity enters and leaves the ventricle. With pacing (pacing spikes are noted on the electrocardiogram), there is pulsus alternans and alternans of the end-diastolic and stroke volume counts. The time-activity curve was not obtained simultaneously with the pressure tracing.

TABLE II Pertinent Data in the 2 Patients After Aortic Valve Replacement

	Patient 1		Patient 2	
	Control	Pacing	Control	Pacing
HR (beats/min)	96	140	80	140
CI-TD (liters/min/m^2)	3.9	3.6	3.4	3.2
PCW (mm Hg)	8	9	19	22
PAP (mm Hg)	13	14	24	30
FAP (mm Hg)	100	100	98	96
EDVI (ml/m^2)	87	55	137	77
ESVI (ml/m^2)	46	29	94	53
EF (%)	47	47	31	31

CI-TD = cardiac index by thermodilution; EDVI = end-diastolic volume index; EF = ejection fraction; ESVI = end-systolic volume index; FAP = mean femoral arterial pressure; HR = heart rate; PAP = mean pulmonary arterial pressure; PCW = mean pulmonary capillary wedge pressure.

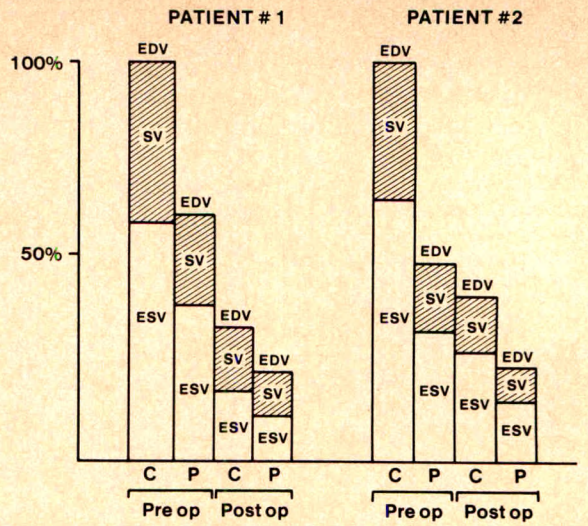

FIGURE 2. Changes in left ventricular volumes with pacing before and after valve replacement. C = control; EDV = end-diastolic volume; ESV = end-systolic volume; P = pacing; Postop = postoperative; Preop = preoperative; SV = stroke volume.

Wenckebach-type atrioventricular block. The control and pacing studies were done 7 to 10 days before and after uneventful AVR.

The pertinent data before replacement are shown in Table I, and after replacement in Table II. Pulsus alternans was not observed with pacing before AVR, but was present in both patients afterwards. The time-activity curves from the LV region also are shown in Figure 1. There is alternation in stroke volume counts with pacing. AVR resulted in a decrease in end-diastolic volume. Since pacing resulted in a decrease in end-diastolic volume before and after AVR, the pacing end-diastolic volume was considerably smaller after than before surgery. AVR resulted in a 67% decrease in end-diastolic volume in the first patient, and a 58% decrease in the second patient. After AVR, pacing resulted in a 79% decrease in end-diastolic volume in the first patient and a 77% decrease in the second compared with preoperative control measurements (Fig. 2). The ejection fraction with pacing was higher in the first patient and unchanged in the second after AVR.

Several mechanisms may contribute to pulsus alternans: alternation in ventricular end-diastolic volume (the Starling mechanism), alternation in contractile force without end-diastolic volume change (the "myocardial" theory), or a combination of both mechanisms.[1,4] Alternation in cardiac cycle length and time available for ventricular filling or relaxation may further influence these basic determining factors. Persistent alternans is associated with relatively severe LV dysfunction and appears to occur mainly on the basis of the myocardial mechanism.[1] In aortic stenosis, alternation of the arterial pulse is smaller than the ventricular alternation, due to the attenuating effect of the valvular obstruction.

Our report suggests that marked reduction in LV end-diastolic volume, induced by atrial pacing after AVR for AR, can precipitate pulsus alternans (Fig. 2). The alternation in end-diastolic volume (Fig. 1) indicates that pulsus alternans occurred on the basis of the

Starling mechanism. It is possible that pulsus alternans, by the same mechanism, may be encountered during sinus tachycardia in the early postoperative period after AVR.

Contrast Echocardiography to Reduce Ionizing Radiation Associated With Cardiac Catheterization During Pregnancy

Uri Elkayam, MD
David Kawanishi, MD
Cheryl L. Reid, MD
P. Anthony N. Chandraratna, MD
Norbert Gleicher, MD
Shahbudin H. Rahimtoola, MD

The use of radiation for diagnostic imaging should be minimized during pregnancy because of hazards to the fetus.[1,2] Cardiac catheterization, however, is sometimes indicated for diagnostic, therapeutic, and prognostic reasons. This report describes the use of two-dimensional (2-D) contrast echocardiography as a substitute for cineangiography in the assessment of cardiac valvular function in pregnancy.

A 23-year-old woman in her 31st week of pregnancy was admitted for dyspnea and palpitations, which started at her 20th gestational week and worsened progressively thereafter. On arrival in the emergency room the respiratory rate was 28 breaths/min, pulse 150 beats/min, and blood pressure 112/76 mm Hg. Examination suggested mitral stenosis and regurgitation (MR), aortic regurgitation, and possible aortic stenosis. The electrocardiogram showed atrial flutter with an atrial rate of 300 beats/min and 2:1 atrioventricular conduction. Right-sided cardiac catheterization was done using a Swan-Ganz catheter under pressure monitoring only without the use of fluoroscopy. A 7Fr pigtail catheter was then placed in the left ventricle with the aid of fluoroscopy. Hemodynamic measurements revealed 17 mm Hg pressure gradient across the mitral valve, but no aortic stenosis. While 2-D echocardiography was performed in multiple views, 10 ml repeated injections of 5% dextrose in water was injected into the left ventricle after vigorous agitation and removal of any visible bubbles. The injection into the left ventricle was immediately followed by complete opacification of the entire left atrium (Fig. 1). The contrast density was less than that in the ventricle, suggesting moderately severe MR. The catheter was then pulled back under pressure monitoring into the aortic root. The tip of the catheter was positioned with the aid of fluoroscopy 1 loop diameter above the aortic valve. The injection into the aortic root was followed by the appearance of microbubbles in the left ventricle that did not completely fill the chamber, suggesting moderate aortic regurgitation. The presence of microbubbles in the left atrium after the aortic root injection was further evidence of the presence and severity of MR (Fig. 2). Because of the inability to precisely assess left ventricular volume and, therefore, the diastolic blood flow across the mitral valve, we could not calculate the mitral valve area. To control the rapid heart rate, propranolol was added to the patient's medical regimen. Because of significant risks of double valve replacement and the already advanced stage of pregnancy, a trial of medical therapy with arteriolar dilators seemed appropriate. The patient was, therefore, started on hydralazine. Her condition improved and she was discharged home on the ninth hospital day. One week after discharge she was readmitted for premature rupture of membranes, and 18 hours later, in her 33rd gestational week, the patient delivered a normal infant whose size was adequate for

gestational age. The course of labor, delivery, and the postpartum period were uneventful.

The significantly increased burden on the cardiovascular system during pregnancy may result in a rapid deterioration of maternal heart disease to a potentially lethal condition. Cardiac catheterization, therefore, is sometimes indicated during pregnancy, especially in patients in whom cardiac surgery is being considered.

Radiologic examination during pregnancy is associated with potential biological risk to the embryo or fetus.[1,2] The risks include resorption or death to the embryo, congential malformations, cancer induction, and genetic changes. The adverse effect of radiation varies with the developmental stage of the fetus, and the likelihood of side effects is linearly proportional to the dose of absorbed radiation.[1] The present study demonstrates the use of contrast echocardiography during cardiac catheterization to collect diagnostic information usually obtained by fluoroscopy or cineangiography, and thus to significantly reduce exposure to x-ray radiation.

Our case supports a previous report by Meltzer et al,[3] who performed cardiac catheterization in a pregnant woman under 2-D echocardiographic control without the use of x-ray radiation. Unlike their experience, however, we could not achieve adequate echocardiographic visualization of the cardiac catheter in the aortic root in our patient. As placement of the cardiac catheter under echocardiographic technique alone in the aortic root and left ventricle is not always possible and is potentially unsafe,[4] the use of x-ray radiation is not completely avoidable. However, utilization of contrast echocardiography can minimize the use of ionizing radiation and, in combination with the hemodynamic data, can provide a reliable assessment of valvular disease. This technique may be used effectively, therefore, in patients with valvular heart disease who are undergoing cardiac catheterization during pregnancy.

Prolonged Survival (62 Years) With Single Ventricle

Harvey L. Goldberg, MD
Kenneth Sniderman, MD
Richard B. Devereux, MD
Aaron Levin, MD

Although single ventricle usually results in death in infancy or childhood, additional obstruction to pulmonary blood flow can permit prolonged, often asymptomatic survival.[1–5] The oldest patient described with single ventricle that we are aware of was 41 years of age at death.[6] We recently studied a man who lived 62 years with a single ventricle.

From the Division of Cardiology, Department of Medicine, Department of Cardiovascular Radiology, and Division of Pediatric Cardiology, Department of Pediatrics, New York Hospital-Cornell Medical Center, New York, New York. Manuscript received March 4, 1983; revised manuscript received April 8, 1983, accepted April 12, 1983.

A precordial murmur was heard at birth. At age 26 years episodic palpitations and fatigue were noted. Cardiac catheterization at age 44 demonstrated an "inoperable hole in the heart" (records not available). The patient continued to experience minimal symptoms until age 62, when dyspnea on exertion appeared. Three months later, when he was in New York Heart Association functional class III from dyspnea and fatigue, cardiac catheterization was performed.

The systemic ventricle was entered from the right atrium. There was no systolic gradient across the aortic outflow tract, but a 130 mm peak-to-peak systolic gradient was present across the infundibulum. Pulmonary arterial pressures were normal. Oximetry demonstrated oxygen saturation in the left ventricle of 83% and femoral artery saturation of 93%. Cut film angiography demonstrated a single large ventricle that was a morphologic left ventricle. The pulmonary artery originated from this ventricle, and subpulmonic stenosis was present. The pulmonary trunk was slightly dilated. There was anterograde flow from the morphologic left ventricle through a bulboventricular foramen into a hypoplastic right ventricle which lay superior and to the left of the left ventricle. The L-transposed aorta originated from the right ventricle. The aortic valve was superior, anterior, and to the left of the pulmonary trunk.

Two months after catheterization second-degree heart block was noted, for which a transvenous pacemaker was

placed. Six months after catheterization he had sudden cardiac arrest despite electrocardiographic evidence of continued pacemaker function. Autopsy was not obtained.

The clinical course of patients with single ventricle is in large part determined by the extent of pulmonic or subpulmonic stenosis. If there is no obstruction to pulmonic flow, congestive heart failure ensues early. With excessive pulmonic stenosis, hypoxia and cyanosis results. However, as this case clearly demonstrates, the "optimal" degree of obstruction of pulmonary blood flow can result in physiologic palliation with prolonged survival.

Our patient provides an excellent example of a hemodynamic phenomenon described by Rahmitoola et al,[6] who noted that L-transposition of the great vessels usually provides preferential streaming of oxygenated blood from the left atrium into the systemic circulation. Thus, our patient had a systemic oxygen saturation of 93%, which was higher than the saturation in the left ventricle. He had neither cyanosis nor polycythemia. The cause of death in our patient is uncertain.

Acknowledgment: We would like to thank Drs. Charles Steinberg and Kalman Berenyi for allowing us to report on their patient, and for follow-up information.

Histiocytoid Cardiomyopathy: A Cause of Sudden Death in Apparently Healthy Infants

Jeffrey E. Saffitz, MD, PhD*
Victor J. Ferrans, MD, PhD
E. Rene Rodriguez, MD
F. Robert Lewis, MD
William C. Roberts, MD

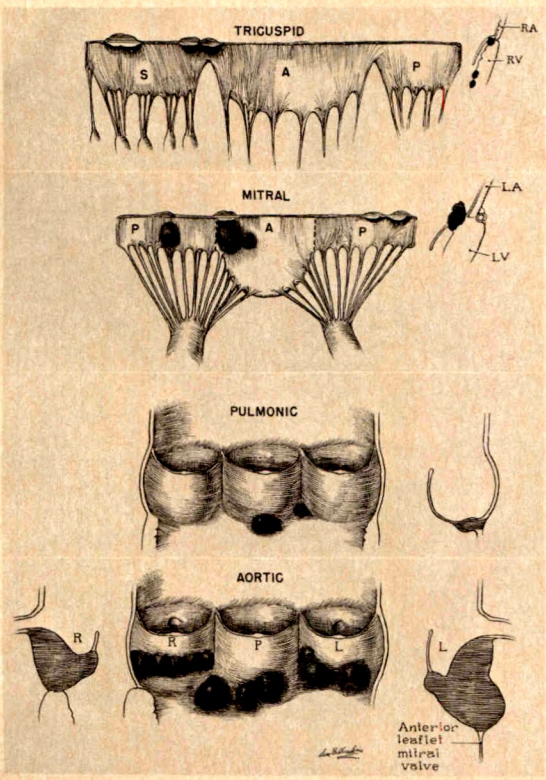

FIGURE 1. Drawing illustrating the distribution of the discrete nodules on the 4 cardiac valves and adjacent myocardial walls. A = anterior leaflet; L = left coronary cusp of aortic valve; LA = left atrium; LV = left ventricle; P = posterior leaflet; R = right coronary cusp of aortic valve; RA = right atrium; RV = right ventricle; S = septal leaflet of tricuspid valve.

Although common in adults, sudden unexpected cardiac death in apparently healthy infants is unusual. Herein we describe a child who died suddenly from infantile cardiomyopathy with histiocytoid myocytes, a poorly understood but clinically and morphologically distinct entity.

A previously healthy-appearing and normally developed 19-month-old white girl was noted to have slight fever (39°C) by her parents and she was given 80 mg of aspirin. Six hours later she awakened, the body temperature was obviously elevated, she quivered with apparent chills and suddenly stopped breathing. At necropsy, the heart weighed 60 g (expected normal weight ≤54 g). Numerous discrete smooth nodules and flat patches of soft yellow-tan tissue were present on all 4 cardiac valves, papillary muscles, and mural endocardial surfaces of both ventricles (Fig. 1 and 2). His-

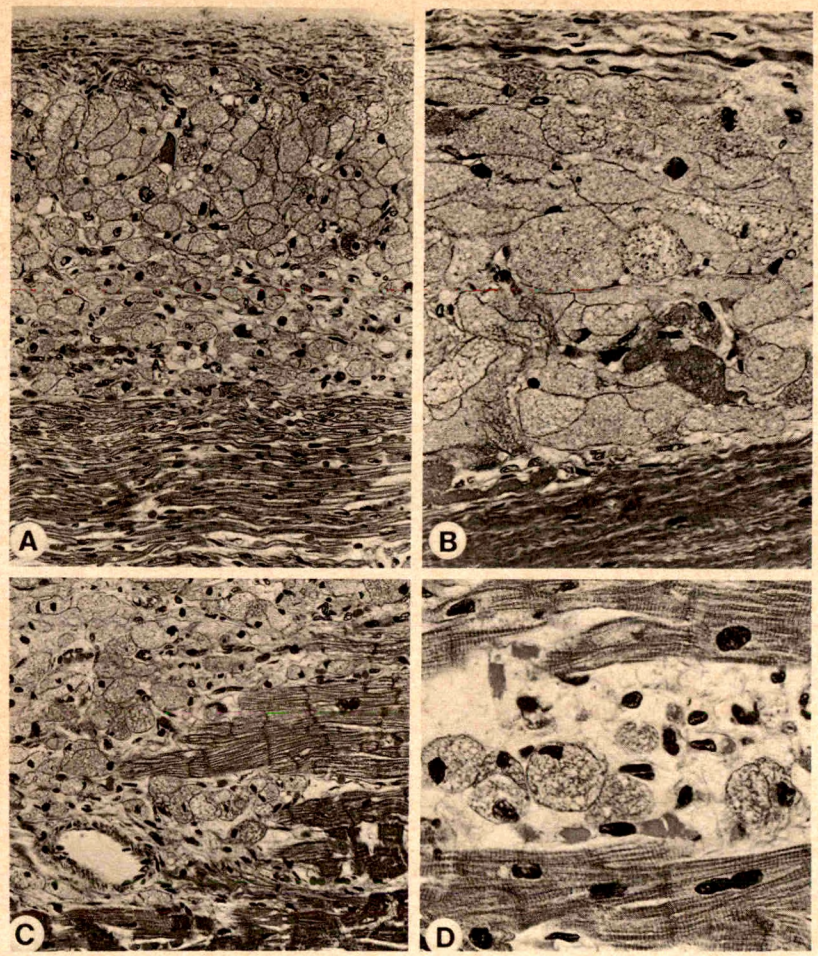

FIGURE 3. Histology of the histiocytoid cells in the patient described. (1-μm–thick plastic sections [glycolmethacrylate embedding] hematoxylin-eosin stain). **A,** section of portion of left ventricular papillary muscle showing a nodule to be composed of numerous histiocytoid cells with large, bizarre nuclei with vacuolated cytoplasm. Myofibrils are not present in these cells, in contrast to subjacent normal myocytes (**bottom**) (× 250, reduced 40%). **B,** higher magnification view of histiocytoid cells (×700, reduced 40%). **C,** transitional zone, showing hypertrophied myocytes adjacent to the histiocytoid cells. Other myocytes (**lower right**) show contraction band necrosis (×250, reduced 40%). **D,** isolated histiocytoid cells located in loose connective tissue between 2 layers of myocytes (×1,000, reduced 40%).

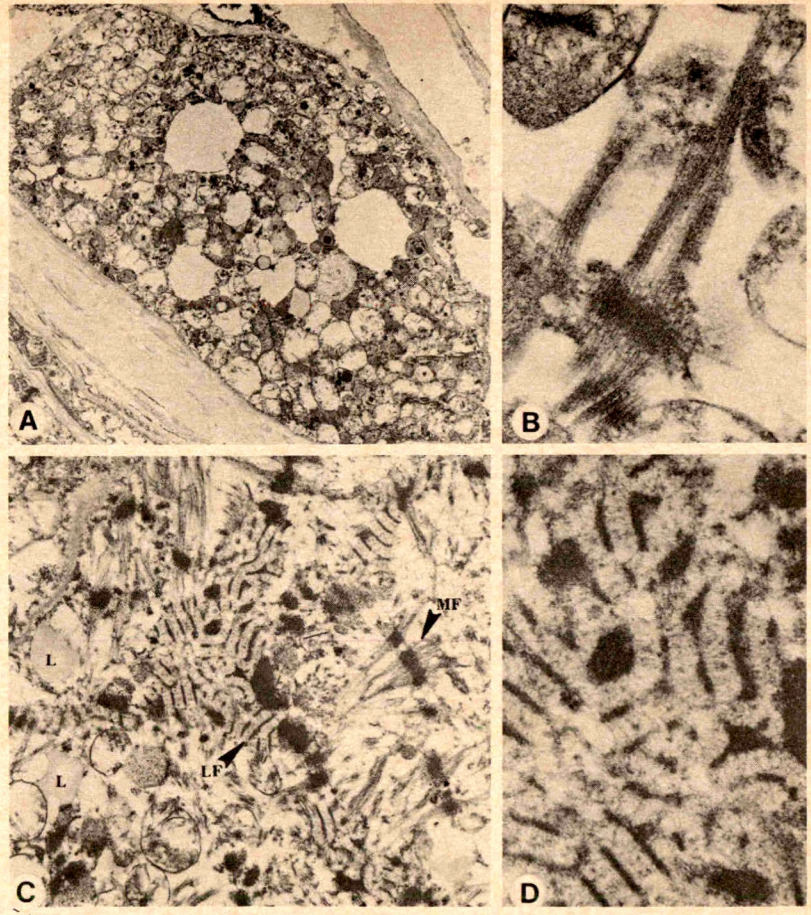

FIGURE 4. Ultrastructure of histiocytoid cells. (Ultrathin sections stained with uranyl acetate and lead citrate.) **A,** low magnification view of isolated histiocytoid cells. The cell lacks contractile elements and contains numerous mitochondria and a few large, clear vacuoles. Many mitochondria are swollen and damaged; others have densely packed cristae. Most mitochondria contain dense inclusions, probably the result of postmortem autolysis (×4,700, reduced 40%). **B,** high magnification view of part of histiocytoid cell, showing remnants of myofibrils, clearly identified by the presence of thick and thin myofilaments and Z band material (×36,000, reduced 40%). **C,** histiocytoid cell contains partially lysed myofibrils (MF), a large cluster of leptofibrils (LF), and several lipid droplets (L) (×18,000, reduced 40%). **D,** higher magnification view of leptofibrils shown in the center of Figure 3C. These structures are composed of periodic bands, with a spacing of 2,000 angstroms (A), of electron-dense material interconnected by filaments of about 50 A in diameter. The function of these structures is unknown (×37,000, reduced 40%).

tologic and ultrastructural examination of the nodules and adjacent myocardium disclosed distinctive histiocytoid cells (Fig. 3) containing abundant mitochondria, occasional lipid droplets, leptofibrils, and fragments of myofibrillar material (Fig. 4).

At least 20 necropsy patients with fatal histiocytoid cardiomyopathy in infancy have been reported.[1,2] In almost all these cases, a seemingly healthy child (aged 2 to 24 months; 90% female) died suddenly, documented in some to be the result of either a supraventricular or a ventricular arrhythmia. All had histiocytoid degeneration of myocardial cells at necropsy. Several patients had developed mild febrile illnesses before death. It appears that the clinical manifestations are due to a cardiomyopathic process leading to myocellular degeneration and transformation of myocytes into cells resembling histiocytes. The presence of leptofibrils in histiocytoid myocytes, first reported by Silver et al,[2] is of unknown significance. The degenerative process must antedate the development of arrhythmia, which occurs late. The cause of the cardiomyopathy is obscure.

Amiodarone Distribution in Human Tissues After Sudden Death During Holter Recording

Aldo P. Maggioni, MD
Angelo Maggi, MD
Alberto Volpi, MD
Vincenzo D'Aranno
Gianni Tognoni, MD
Paolo Giani, MD

Death of a Holter-monitored patient enrolled in a controlled evaluation of the antiarrhythmic efficacy of amiodarone is of specific interest on account of the concomitant information it provides on blood and tissue drug levels.

A 60-year-old man was admitted to the hospital for investigation of recurrent episodes of palpitation. Previously, he had a nontransmural inferior myocardial infarction that healed. Thereafter, he had rare episodes of angina pectoris. Blood pressure was 135/80 mm Hg. Precardial endings were normal. Resting electrocardiogram showed a small Q wave in leads II, III, and aVF, a normal repolarization phase, and monomorphous ventricular extrasystoles. He entered a controlled trial where the efficacy of amiodarone, 400 mg and 200 mg, was tested in successive periods of 28 days, according to the scheme presented in Table I, which also reports the results of amiodarone blood levels and of thyroid hormone determinations taken at the intervals planned in the protocol. The patient was treated with nifedipine (40 mg/day) for stable effort angina. The patient died suddenly after ventricular fibrillation at the time of the scheduled hospital control, 20 minutes after starting the 24-hour Holter monitoring. At necropsy, parts of organs were sampled, and analyzed by the standard method used in our laboratory.[1] The amiodarone concentration in various tissues and ratios of tissue concentration to steady state blood levels (0.94 μg/ml) are reported in Figure 1.

From the Laboratory of Clinical Pharmacology, Mario Negri Institute, Milan, Italy. Manuscript received December 9, 1982; revised manuscript received April 11, 1983, accepted April 12, 1983.

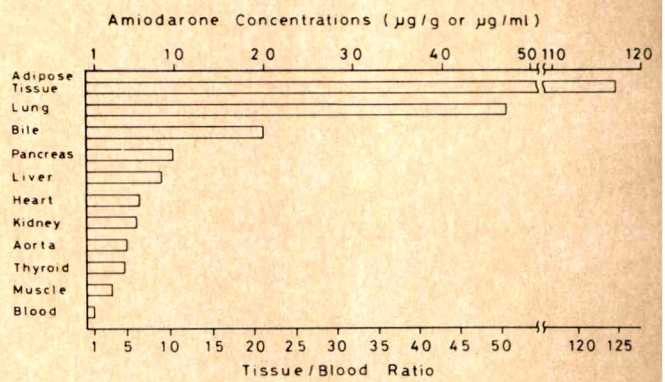

FIGURE 1. Amiodarone distribution in various tissues.

TABLE I Study Protocol and Biochemical Profile

	Day 0	Day 28	Day 56
	↑ Baselines Values	Amiodarone 400 mg/day ↑ 1st Control	Amiodarone 200 mg/day ↑ 2nd Control
Thyroid hormones			
Total thyroxine (TT_4) (nmol/liter)	120	136	130
Free thyroxine (FT_4) (pmol/liter)	11.2	12.7	13.8
Total triiodothyronine (TT_3) (nmol/liter)	2.1	2.0	3.2
Free triiodothyronine (FT_3) (pmol/liter)	6.2	5.3	10.1
Thyroid-stimulating hormone (TSH) (μmol/ml)	2.2	1.2	0.6
Blood amiodarone level (μg/ml)	0	0.95	0.94

The case described here represents the first amiodarone-treated patient for whom a fully documented report is available at the occurrence of sudden death. According to the criteria of the study protocol[2,3] the patient had been classified among the responders to antiarrhythmic therapy and after the first period of the trial his subjective report did not suggest any relevant symptoms during the month before sudden death. Examination the day of death gave findings similar to the previous ones if one excludes an increase in heart rate (from 59 to 75 beats/min). The possible relation of amiodarone treatment with the thyroid status[4] suggests the importance of close monitoring of thyroid function. No clear inference could be drawn from absolute drug concentrations or their ratios. The 2 different regimens of amiodarone (400 and 200 mg) in the 2 study periods did not seem to modify blood drug concentrations, which, however, were not correlated to drug efficacy. The pattern of distribution of amiodarone in various organs confirms the expected preferential concentration in lipid-rich tissues. The very high ratio for lungs, although not associated with any clinical or objective findings, should be viewed in the light of repeated reports of relevant pulmonary side effects.[5] The relatively small amount of amiodarone found in the thyroid gland could support the hypothesis of a peripheral action of the drug.[6] Conversely, the relatively high whole heart tissue concentration reveals little about the level-efficacy relationship.

Severe Mitral Regurgitation Immediately After Mitral Valve Replacement With a Parietal Pericardial Bovine Bioprosthesis

Marc A. Silver, MD
Philip R. Oranburg, MD
William C. Roberts, MD

From the Pathology Branch, National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland.

Manuscript received and accepted April 5, 1983.

The occurrence of severe mitral regurgitation (MR) immediately after mitral valve replacement (MVR) is exceedingly rare. One cause is interference with closure of a prosthetic occluder by the left ventricular wall, calcific deposits, or residual unexcised mitral leaflet or chordae tendineae.[1] Another cause is incomplete obliteration by suture of the space between the prosthetic or bioprosthetic ring and the native anulus, resulting in a paraanular communication.[1] A third and hitherto unreported cause of severe MR immediately after MVR by a bioprosthesis is described in the patient below.

A 64-year-old man who had had a precordial systolic murmur for many years had been asymptomatic until 25

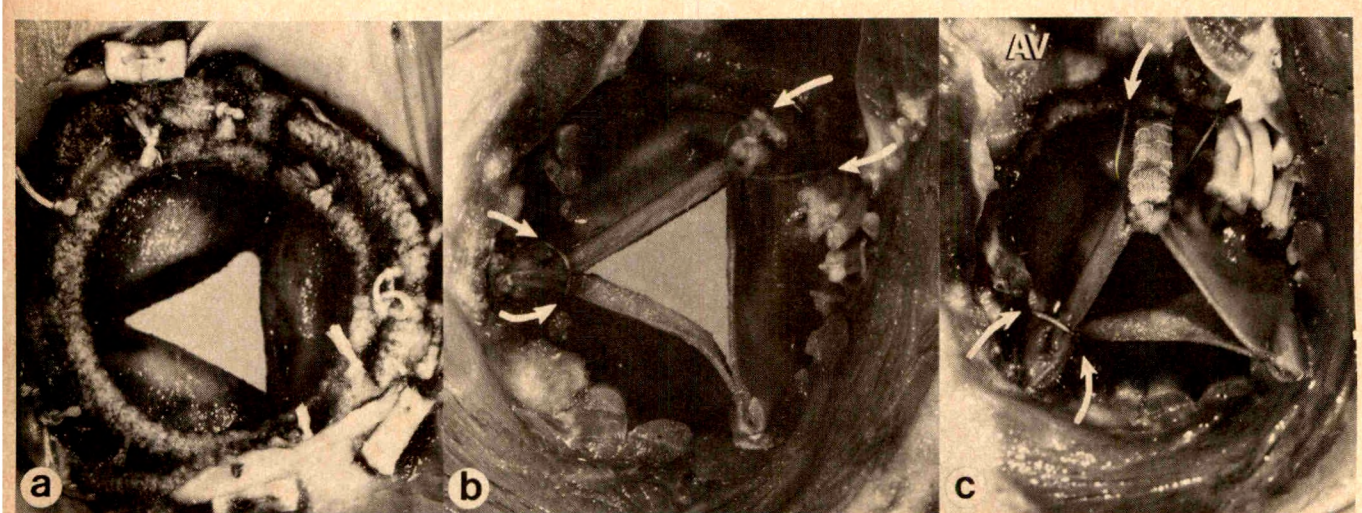

FIGURE 1. Mitral bioprosthesis in the patient described. **a,** view from left atrium showing a triangular orifice. **b and c,** 2 views from the left ventricular aspect. The **arrows** point to the 2 sutures which encircled the stents, causing tautness of the cusps and preventing them from coapting during ventricular systole.

days before MVR, when signs of active infective endocarditis appeared; severe congestive heart failure followed shortly thereafter. Group B beta hemolytic streptococcus was grown on blood cultures. A grade 3/6 precordial apical systolic blowing murmur consistent with MR was audible. The pulmonary arterial wedge mean pressure was 35, V-wave 50, and pulmonary arterial pressure 57/20 mm Hg. At MVR, a vegetation was present on the posterior mitral leaflet to which several chordae had ruptured; the leaflet appeared to prolapse toward left atrium. The purely regurgitant valve was replaced with a 25-mm Ionescu-Shiley bioprosthesis. The patient's early postoperative course was characterized by systemic hypotension and coma. A murmur consistent with MR was heard on precordial examination 2 days after operation. He died 8 days after operation, never having regained consciousness. At necropsy, the heart weighed 690 g. Sutures surrounded 2 of the 3 stents of the mitral bioprosthesis, causing a straight-line stretching of the margins of the bioprosthetic cusps between the 3 commissures. The result was a triangular-shaped severely incompetent bioprosthetic orifice (Fig. 1).

Thus, sutures encircling 2 of the 3 bioprosthetic stents tautened the cusps, producing severe MR. The left atrium should not be closed after MVR until it is clear that the cusps of a tissue valve or the occluder of a mechanical valve[2] are freely mobile.

RETRACTION OF A REPORT PUBLISHED IN THE AJC

In response to the announcement by Harvard University that John R. Darsee, MD, fabricated research data while serving as a research fellow in their School of Medicine, we initiated an extensive investigation by both internal and external committees of Dr. Darsee's work at Emory University. This letter concerns a publication in *The American Journal of Cardiology* that was authored by Dr. Darsee: "Transcutaneous Doppler method of measuring cardiac output—II. Noninvasive measurement by transcutaneous Doppler aortic blood velocity integration and M mode echocardiography," by Darsee JR, Walter PF, and Nutter DO (Am J Cardiol 1980;26:613–618).

The original Doppler records collected and analyzed by Dr. Darsee were not available for review by our investigative committees. Because we cannot validate the data that formed the basis for this article, and in view of the widespread evidence of fraudulent practice in other publications authored by Dr. Darsee, we wish to retract this report.

We apologize to the Editor-in-Chief and the *Journal* for any embarrassment and inconvenience that might result from our investigation of Dr. Darsee's research activities and publications.

RETRACTION OF A REPORT PUBLISHED IN THE AJC

Harvard University and the National Institutes of Health have both completed committee reports that concluded that John R. Darsee, MD, fabricated research data while serving as a research fellow at Harvard University and performing research supported by the National Heart, Lung, and Blood Institute.

An intensive investigation has been performed by both internal and external committees of Emory University concerning Dr. Darsee's previous publications while at Emory University. This letter concerns the report "Transcutaneous method of measuring Doppler cardiac output—I. Comparison of transcutaneous and juxta-aortic Doppler velocity signals with catheter and cuff electromagnetic flowmeter measurements in closed and open chest dogs," by Darsee JR, Mikolich JR, Walter PF, and Schlant RC (Am J Cardiol 1980;46:607–612).

In our investigation we were unable to obtain and verify the original data reported in the above article. Due to our inability to verify the observations reported in this paper as well as the widespread evidence of fraudulent practice in other abstracts and reports authored by Dr. Darsee, we believe that the work described in this report should be considered of uncertain validity. We wish to retract this report.

We apologize to the *Journal* and to its readers for any embarrassment and inconvenience that might have resulted from this publication and from our investigation of Dr. Darsee's research activities and publications.

RETRACTION OF 3 ABSTRACTS PUBLISHED IN THE AJC

In response to the announcement by Harvard University that John R. Darsee, MD had fabricated research data while serving as a research fellow in their School of Medicine, we initiated an extensive investigation by both internal and external committees of Dr. Darsee's work at Emory University. This letter concerns 3 abstracts authored by Dr. Darsee and published in *The American Journal of Cardiology:*

> Darsee JR, Miklozek CL, Heymsfield SB, Nutter DO. Complement-resistant lymphocytes in mitral valve prolapse. Am J Cardiol 1979;43:367.
>
> Darsee JR, Fincher RE, Fincher M, Miklozek CL, Someren AO, Hurst JW. The heart in pancreatitis: a combined clinicopathologic study of 128 cases. Am J Cardiol 1980;45:395.
>
> Darsee JR, Anton S, Miklozek CL, Someren AO. Is nonfamilial asymmetric septal hypertrophy a different histological disorder? Am J Cardiol 1980;45:492.

The Emory University School of Medicine faculty members whose names appear on these abstracts did not participate in the reported research or review the abstracts before their submission. In most cases the co-authors were not aware that the abstracts had been submitted or published. Most of these abstracts were submitted for publication or appeared in print after Dr. Darsee left Emory University (July 1979). For the aforestated reasons and in view of the widespread evidence of fradulent practice in other reports authored by Dr. Darsee, we believe that these abstracts are invalid, and in some cases it seems likely that the data were fabricated. We request that the abstracts be retracted.

We apologize to the Editor-in-Chief and the *Journal* for any embarrassment and inconvenience that might result from our investigation of Dr. Darsee's research activities and publications.

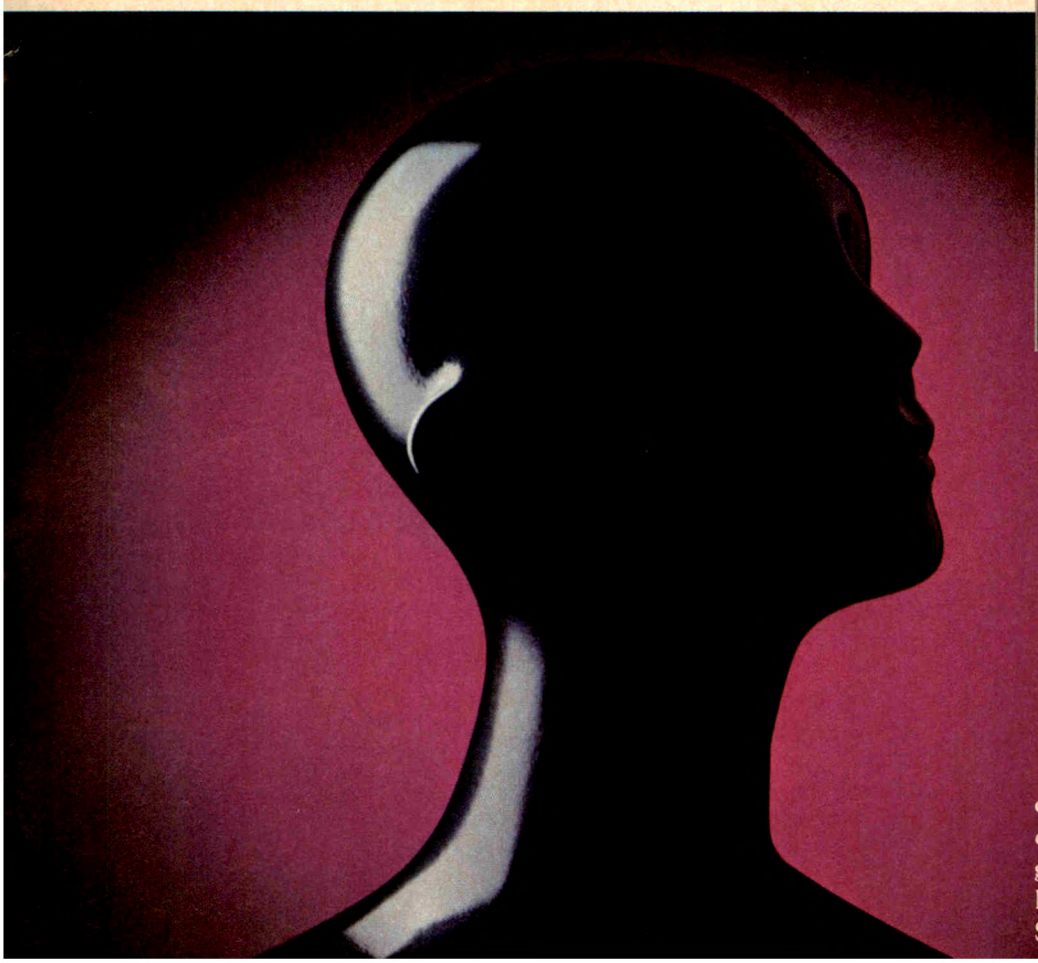
RETRACTION OF A PUBLISHED ABSTRACT

Irregularities in data collected in my laboratory by a collaborator, described in *Harvard University Gazette* (February 18, 1983;78:1) and *Science* (1983;220:31–35) have brought into question the validity of the data listed in the abstract below, which was retracted as a full-length publication. Because of these circumstances, it is my opinion that this abstract should be retracted: Darsee JR, Kloner RA. The no-reflow phenomenon: not a time limiting factor for reperfusion following coronary occlusion (abstr). Am J Cardiol 1980;45:394.

Robert A. Kloner, MD, PhD
Boston, Massachusetts

* Letters (from the United States) concerning a particular article in the *Journal* must be received within 2 months of the article's publication, and should be limited (with rare exceptions) to 2 double-spaced typewritten pages. Two copies must be submitted.

THE FUTURE HAS A WAY OF ECHOING THE PAST.



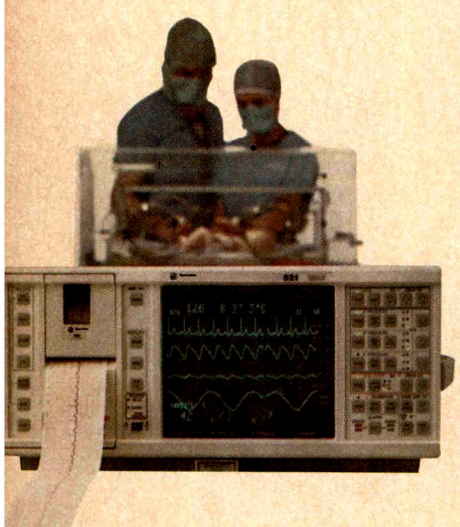
Today, we're EkoLine, one of the fastest growing companies in Echocardiography. But you probably knew us by our first name, Smith Kline Instruments.

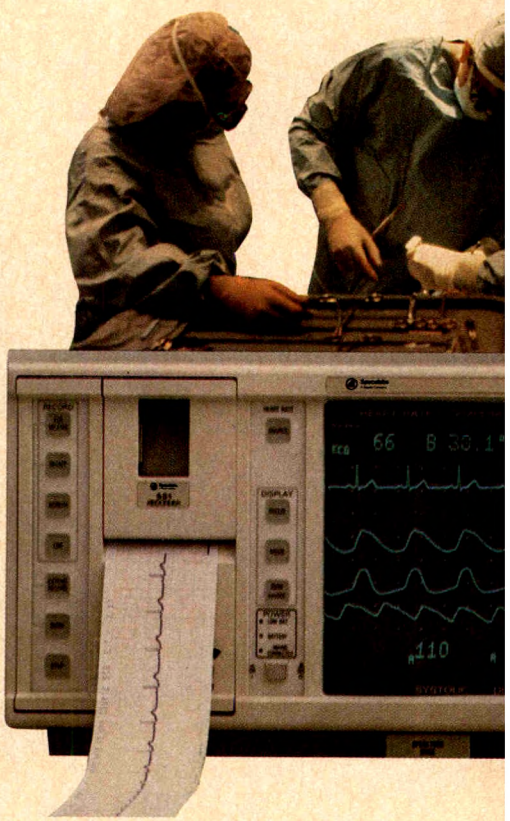
NOW YOU HAVE A CHOICE

Now there is more than one company which can provide you with hospital-wide patient monitoring equipment. The new choice is Spacelabs: for every need, for every level of monitoring required, there is a Spacelabs monitor or system to do the job—accurately, reliably, affordably.

MORE MONITORS...FOR MORE AREAS OF THE HOSPITAL

We have incorporated the well-known portable monitors of Vitatek and the automated noninvasive monitors of Vita-Stat with Spacelabs' patient monitors. The result is a comprehensive line of patient monitoring equipment to meet the broad needs of your hospital...from a simple noninvasive blood pressure monitor to a most sophisticated arrhythmia detection system... from basic, economical stand-alone monitors to a versatile, flexible, multi-bed system, either preconfigured or modular for even greater flexibility...including portable monitors that move with the patient from surgery to the recovery room to the surgical ICU, and telemetry units for ambulatory patients. In fact, every patient who needs monitoring—from neonate to adult, from outpatient to high-risk surgical patient, from acutely ill cardiac patient to one who is in rehabilitation—can benefit from a Spacelabs monitor.





ER REHAB OR RR CCU

Spacelabs
A Squibb Company

MORE EFFICIENT SERVICE NETWORK

The service representatives from our companies are now united into one finely-tuned network—a nationwide service organization dedicated *solely* to patient monitoring equipment, with technical specialists standing by across the country to provide assistance whenever and wherever needed. These specialists understand the complexity of systems and are sensitive to the critical nature of your service needs.

MORE PRODUCT DEVELOPMENT RESOURCES

Uniting the R&D, engineering and quality assurance resources of these companies has produced a large pool of expert design and engineering talent. These individuals are focused sharply on bringing monitoring innovations into clinical practice quickly, efficiently and economically.

As a part of the Squibb Corporation—a multi-billion-dollar healthcare company committed to improving patient care—Spacelabs faces an exciting future, offering your hospital more than just another choice. Whether you need a single monitor or a complete system for one department, or if you are considering standardizing all monitoring equipment throughout your hospital, *call*

800-251-9910

to find out why Spacelabs can be your best choice.

To contain the risk of life-threatening V-Fib in the patient with serious V-Tach

Bretylol® (bretylium tosylate)

Electrical instability often underlies hemodynamically unstable V-Tach, breakthrough V-Tach, and recurrent V-Tach. This hidden instability carries with it the danger of life-threatening V-Fib.

Because you know V-Tach is often the precursor of ventricular fibrillation...

Use Bretylol to get added *insurance against* and *continued protection from* the underlying electrical instability which can lead to V-Fib.

Bretylol provides unique antifibrillatory action

- ***Bretylol suppresses reentry*** **by helping to equalize the electrophysiological differences between injured and normal ventricular muscle.[1,2*]**
- ***Bretylol raises the V-Fib threshold*** **almost three times control level.[3*]**
- ***Bretylol*** **also *reduces the energy required for defibrillation*** **by as much as one-third.[4,5*]**

*Based on laboratory animal studies.

© 1983 American Critical Care
Division of American Hospital Supply Corporation

Bretylol is indicated for first-line treatment of V-Fib and for protection against V-Fib. In patients with life-threatening ventricular arrhythmias other than V-Fib and n at risk of V-Fib, Bretylol is indicated if the arrhythmia has failed to respond to adequa doses of a first-line agent such as lidocaine.

The most common side effect of Bretylol is postural hypotension. Some degree of hypotension is present in approximately 50 percent of patients while they are supine Please see following page for a brief summary of the prescribing information.

For further information please contact the Medical Services Department, American Critical Care, division of American Hospital Supply Corporation, 1600 Waukegan Road, McGaw Park, IL 60085, Phone 800/323-4980.

Bretylol®
(bretylium tosylate)

Brief summary of prescribing information

INDICATIONS—BRETYLOL is indicated in the prophylaxis and therapy of ventricular fibrillation.

BRETYLOL is also indicated in the treatment of life-threatening ventricular arrhythmias, such as ventricular tachycardia, that have failed to respond to adequate doses of a first-line antiarrhythmic agent, such as lidocaine.

Use of BRETYLOL should be limited to intensive care units, coronary care units or other facilities where equipment and personnel for constant monitoring of cardiac arrhythmias and blood pressure are available.

Following injection of BRETYLOL there may be a delay of 20 minutes to 2 hours in the onset of antiarrhythmic action, although it appears to act within minutes in ventricular fibrillation. The delay in effect appears to be longer after intramuscular than after intravenous injection.

CONTRAINDICATIONS—There are no contraindications to use in treatment of ventricular fibrillation or life-threatening refractory ventricular arrhythmias.

WARNINGS—1. Hypotension: Administration of BRETYLOL regularly results in postural hypotension, subjectively recognized by dizziness, lightheadedness, vertigo or faintness. Some degree of hypotension is present in about 50% of patients while they are supine. Hypotension may occur at doses lower than those needed to suppress arrhythmias.

> Patients should be kept in the supine position until tolerance to the hypotensive effect of BRETYLOL develops. Tolerance occurs unpredictably but may be present after several days.

Hypotension with supine systolic pressure greater than 75 mm Hg need not be treated unless there are associated symptoms. If supine systolic pressure falls below 75 mm Hg, an infusion of dopamine or norepinephrine may be used to raise blood pressure. When catecholamines are administered, a dilute solution should be employed and blood pressure monitored closely because the pressor effects of the catecholamines are enhanced by BRETYLOL. Volume expansion with blood or plasma and correction of dehydration should be carried out where appropriate.

2. Transient Hypertension and Increased Frequency of Arrhythmias: Due to the initial release of norepinephrine from adrenergic postganglionic nerve terminals by BRETYLOL, transient hypertension or increased frequency of premature ventricular contractions and other arrhythmias may occur in some patients.

3. Caution During Use with Digitalis Glycosides: The initial release of norepinephrine caused by BRETYLOL may aggravate digitalis toxicity. When a life-threatening cardiac arrhythmia occurs in a digitalized patient, BRETYLOL should be used only if the etiology of the arrhythmia does not appear to be digitalis toxicity and other antiarrhythmic drugs are not effective. Simultaneous initiation of therapy with digitalis glycosides and BRETYLOL (bretylium tosylate) should be avoided.

4. Patients with Fixed Cardiac Output: In patients with fixed cardiac output (i.e., severe aortic stenosis or severe pulmonary hypertension) BRETYLOL should be avoided since severe hypotension may result from a fall in peripheral resistance without a compensatory increase in cardiac output. If survival is threatened by the arrhythmia, BRETYLOL may be used but vasoconstrictive catecholamines should be given promptly if severe hypotension occurs.

USE IN PREGNANCY—The safety of BRETYLOL in human pregnancy has not been established. However, as the drug is intended for use only in life-threatening situations, it may be used in pregnant women when its benefits outweigh the potential risk to the fetus.

USE IN CHILDREN—The safety and efficacy of this drug in children has not been established. BRETYLOL has been administered to a limited number of pediatric patients, but such use has been inadequate to define fully proper dosage and limitations for use.

PRECAUTIONS—1. Dilution for Intravenous Use: BRETYLOL should be diluted (one part BRETYLOL with four parts of Dextrose Injection, USP or Sodium Chloride Injection, USP) prior to intravenous use. Rapid intravenous administration may cause severe nausea and vomiting. Therefore, the diluted solution should be infused over a period greater than 8 minutes. In treating existing ventricular fibrillation BRETYLOL should be given as rapidly as possible and may be given without dilution.

2. Use of Various Sites for Intramuscular Injection: When injected intramuscularly, not more than 5 ml should be given in a site, and injection sites should be varied since repeated intramuscular injection into the same site may cause atrophy and necrosis of muscle tissue, fibrosis, vascular degeneration and inflammatory changes.

3. Reduce Dosage in Impaired Renal Function: Since BRETYLOL is excreted principally via the kidney, the dosage interval should be increased in patients with impaired renal function.

ADVERSE REACTIONS—Hypotension and postural hypotension have been the most frequently reported adverse reactions (see Warnings section). Nausea and vomiting occurred in about three percent of patients, primarily when BRETYLOL was administered rapidly by the intravenous route (see Precautions section). Vertigo, dizziness, light-headedness and syncope, which sometimes accompanied postural hypotension, were reported in about 7 patients in 1000.

Bradycardia, increased frequency of premature ventricular contractions, transitory hypertension, initial increase in arrhythmias (see Warnings section), precipitation of anginal attacks, and sensation of substernal pressure have also been reported in a small number of patients, i.e., approximately 1-2 patients in 1000.

Renal dysfunction, diarrhea, abdominal pain, hiccups, erythematous macular rash, flushing, hyperthermia, confusion, paranoid psychosis, emotional lability, lethargy, generalized tenderness, anxiety, shortness of breath, diaphoresis, nasal stuffiness and mild conjunctivitis, have been reported in about 1 patient in 1000. The relationship of BRETYLOL administration to these reactions has not been clearly established.

HOW SUPPLIED—NDC 0094-0012-10: 10 ml ampul containing 500 mg bretylium tosylate in Water for Injection, USP pH adjusted, when necessary, with dilute hydrochloric acid or sodium hydroxide. Sterile, non-pyrogenic.

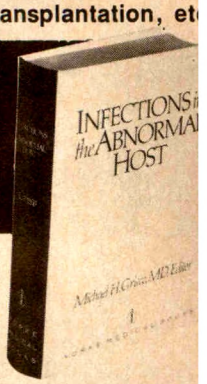
INFECTIONS
IN THE ABNORMAL HOST

Edited by Michael H. Grieco, M.D.
Text by 47 Specialists. Illustrated with 147 Drawings and Photos, 78 in Full Color



Infections in the Abnormal Host discusses in 36 revealing chapters the mechanics of host defenses . . . the various underlying disorders and the latest treatments by chemotherapy, management of agranulocytosis, immunological reconstitution, passive and active immunotherapy, and immunostimulation.

Consultation and study of **Infections** will help you understand diagnose, and manage the many infections which strike patient whose defense mechanisms are down.

Check this list of chapters

PART I HOST DEFENSES

• Introduction to the Abnormal Host and Complicating Infections • Th Neutrophil in Host Defense: Congenital, Acquired and Drug-induced Ab normalities • The Complement System in Human Disease • Structure an Function of Immunoglobulins • Human Lymphocyte Subpopulations Surface, Intracellular, Enzymatic Markers and Functions • Congenita and Acquired Primary Disorders of B and T Lymphocyte Function • Drug induced B and T Lymphocyte and Monocyte Dysfunction • Cutaneous Pulmonary, Gastrointestinal and Genitourinary Defense Mechanisms an Relationship to Nosocomial Infections • The Effects of Malnutrition o Host Responses and the Metabolic Sequelae of Infections • Humoral an Cellular Responses to Infection

PART II INFECTIONS ASSOCIATED WITH THE ABNORMAL HOST

• Pyogenic Bacterial Infections • Higher Bacterial and Fungal Infections Mycobacterial Infections • Viral and Chlamydial Infections • Protozoa and Helminthic Infections • Infections Complicating the Transfusion Blood, Blood Products, Animal Exposure and Animal Products • Infec tions Complicating the Alcoholic Host • Infections in Parenteral Narcoti and Drug Abusers • Infections Complicating Uremia and Organ Trans plantation • Infections in Patients with Neoplastic Diseases • Infection Complicating Diabetes Mellitus • Diagnosis and Treatment of Diffus Pneumonias • Host Deficiency States and Central Nervous System Infec tions • Genitourinary Infections • Infections Complicating the Rheumati Diseases • Endovascular and Prosthetic Implant Infections • Intraocula Manifestations of Systemic Infections • Selected Histopathologic Respon ses • The Microbiology Laboratory in Diagnosis and Therapy • Infection Complicating Surgical or Functional Splenectomy and Gastrectomy

PART III MANAGEMENT

• Antimicrobial Therapy in the Compromised Host: Resistance, Pharma cology and Toxicity • Chemotherapy for Viral and Chlamydial Infections Chemotherapy for Protozoal and Helminthic Infections • Infection Preven tion in Patients with Cancer and Granulocytopenia • Immunologic Re constitution • Gamma Globulin and Vaccine Therapy • Index

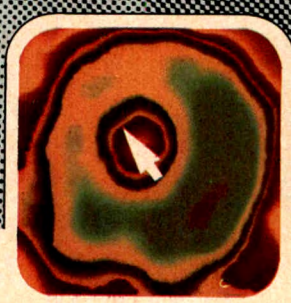
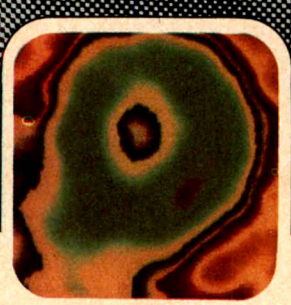
PRIORITIES IN TREATMENT OF ANXIOUS



Thallium scintiscan after exercise, showing marked anterior wall perfusion defect (arrow) before angioplasty.[1]



Postangioplasty thallium scintiscan showing no perfusion defect after peak exercise.[1]

FIRST THE BENEFITS OF PRIMARY MEASURES

Never before have physicians had so many resources for dealing effectively with cardiac disease. Now numerous cardiovascular medications are available—antianginal preparations, antihypertensives, diuretics, calcium antagonists, digitalis, quinidine, vasodilators. Besides these many agents, there are proven surgical procedures such as coronary bypass and valve replacement—and nonsurgical procedures such as angioplasty, which is fast becoming an accepted method of treating severe arterial stenoses.[1] The efficacy of angioplasty is illustrated in the above scintiscans. Yet, even with so many primary measures for improving the patient's cardiovascular status, secondary problems may adversely affect convalescence. One such problem may be excessive anxiety.[2]

SECOND THE BENEFITS OF ADJUNCTIVE ANTIANXIETY MEASURES

Anxiety in cardiac patients during recovery is a frequent response to symptoms such as chest pain, arrhythmias, breathlessness and weakness.[3] Often, anxiety can be allayed by supportive measures, such as encouraging the patient to express his fears openly, offering reassuring explanations for postcoronary symptoms and, when necessary, prescribing antianxiety medication.[3] For valid reasons, the medication often chosen is Valium® (diazepam/Roche). Its record of efficacy and safety is universally acknowledged. Little or no cardiotoxicity has been reported. Also, Valium is used with most primary cardiac medications. As with all CNS-acting agents, patients should be cautioned against drinking alcohol and against engaging in activities requiring complete mental alertness. Used judiciously, Valium can be a valuable adjunct to rehabilitative measures and can help the cardiac patient employ his own coping devices to good effect.

VALIUM®(IV)

diazepam/Roche

2-mg, 5-mg, 10-mg scored tablets

Second to none in pharmacotherapy of anxiety

Please see next page for summary of complete product information.

ROCHE®

VALIUM® (IV)
diazepam/Roche

Before prescribing, please consult complete product information, a summary of which follows:

Indications: Management of anxiety disorders, or short-term relief of symptoms of anxiety. Anxiety or tension associated with the stress of everyday life usually does not require treatment with an anxiolytic. Symptomatic relief of acute agitation, tremor, delirium tremens and hallucinosis due to acute alcohol withdrawal; adjunctively in skeletal muscle spasm due to reflex spasm to local pathology; spasticity caused by upper motor neuron disorders; athetosis; stiff-man syndrome; convulsive disorders (not as sole therapy).
The effectiveness of Valium in long-term use, that is, more than 4 months, has not been assessed by systematic clinical studies. The physician should periodically reassess the usefulness of the drug for the individual patient.

Contraindicated: Known hypersensitivity to the drug. Children under 6 months of age. Acute narrow glaucoma; may be used in patients with open angle glaucoma who are receiving appropriate therapy.

Warnings: Not of value in psychotic patients. Caution against hazardous occupations requiring complete mental alertness. When used adjunctively in convulsive disorders, possibility of increase in frequency and/or severity of grand mal seizures may require increased dosage of standard anticonvulsant medication; abrupt withdrawal may be associated with temporary increase in frequency and/or severity of seizures. Advise against simultaneous ingestion of alcohol and other CNS depressants. Withdrawal symptoms similar to those with barbiturates and alcohol have been observed with abrupt discontinuation, usually limited to extended use and excessive doses. Infrequently, milder withdrawal symptoms have been reported following abrupt discontinuation of benzodiazepines after continuous use, generally at higher therapeutic levels, for at least several months. After extended therapy, gradually taper dosage. Keep addiction-prone individuals under careful surveillance because of their predisposition to habituation and dependence.

Usage in Pregnancy: **Use of minor tranquilizers during first trimester should almost always be avoided because of increased risk of congenital malformations as suggested in several studies. Consider possibility of pregnancy when instituting therapy; advise patients to discuss therapy if they intend to or do become pregnant.**

Precautions: If combined with other psychotropics or anticonvulsants, consider carefully pharmacology of agents employed; drugs such as phenothiazines, narcotics, barbiturates, MAO inhibitors and other antidepressants may potentiate its action. Usual precautions indicated in patients severely depressed, or with latent depression, or with suicidal tendencies. Observe usual precautions in impaired renal or hepatic function. Limit dosage to smallest effective amount in elderly and debilitated to preclude ataxia or oversedation.
The clearance of Valium and certain other benzodiazepines can be delayed in association with Tagamet (cimetidine) administration. The clinical significance of this is unclear.

Side Effects: Drowsiness, confusion, diplopia, hypotension, changes in libido, nausea, fatigue, depression, dysarthria, jaundice, skin rash, ataxia, constipation, headache, incontinence, changes in salivation, slurred speech, tremor, vertigo, urinary retention, blurred vision. Paradoxical reactions such as acute hyperexcited states, anxiety, hallucinations, increased muscle spasticity, insomnia, rage, sleep disturbances, stimulation have been reported; should these occur, discontinue drug. Isolated reports of neutropenia, jaundice; periodic blood counts and liver function tests advisable during long-term therapy.

Dosage: Individualize for maximum beneficial effect. *Adults:* Anxiety disorders, symptoms of anxiety, 2 to 10 mg b.i.d. to q.i.d.; alcoholism, 10 mg t.i.d. or q.i.d. in first 24 hours, then 5 mg t.i.d. or q.i.d. as needed; adjunctively in skeletal muscle spasm, 2 to 10 mg t.i.d. or q.i.d.; adjunctively in convulsive disorders, 2 to 10 mg b.i.d. or q.i.d. *Geriatric or debilitated patients:* 2 to 2½ mg, 1 or 2 times daily initially, increasing as needed and tolerated. (See Precautions.) *Children:* 1 to 2½ mg t.i.d. or q.i.d. initially, increasing as needed and tolerated (not for use under 6 months).

How Supplied: For oral administration, Valium scored tablets—2 mg, white; 5 mg, yellow; 10 mg, blue—bottles of 100 and 500; Prescription Paks of 50, available in trays of 10. Tel-E-Dose® packages of 100, available in trays of 4 reverse-numbered boxes of 25, and in boxes containing 10 strips of 10.

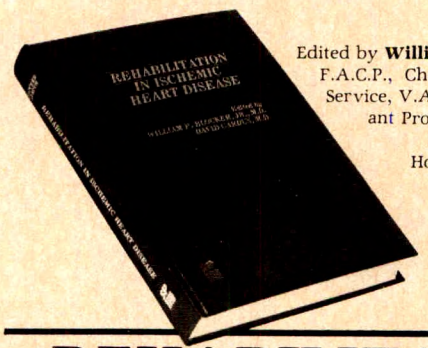
This book contains the most complete list of cardiac risk factors to be found in any text . . .



Edited by **William P. Blocker, Jr., M.D.**, F.A.C.P., Chief, Rehabilitation Medicine Service, V.A. Hospital, Houston, Assistant Professor of Physical Medicine Baylor College of Medicine Houston, and **David Cardus** M.D., F.A.C.C., Professor of Physiology and Rehabilitation Baylor College of Medicine, Houston, Texas

REHABILITATION IN ISCHEMIC HEART DISEASE

Heavily illustrated, this volume presents 60 self-contained chapters dealing with *all* aspects of rehabilitation of the patient with ischemic heart disease. The 45 noted contributors discuss topics such as: designing a cardiac rehabilitation center; methods of rehabilitation for the stroke patient, amputee, spinal cord injury patient who has had a heart attack; equipment needs for a cardiac rehabilitation center; and legal responsibilities of the physicians and therapists.

All major aspects, from epidemiology and pathogenesis through prevention and education are covered, including ambulatory monitoring of electrocardiogram and blood pressure; evaluation of degree of disability; and pathogenesis of atherosclerosis. This book contains the *most complete* list of cardiac risk factors to be found in any text. This encyclopedic guide to the total care and rehabilitation of cardiac patients is written for *every* member of the cardiac rehabilitation team.

Patients bothered by too much caffeine can still enjoy coffee

When you treat a patient whose hypertension, anxiety, insomnia or cardiac condition might be aggravated by too much caffeine, diet modifications may be indicated. Often this involves eliminating favorite foods and beverages. But there's one beverage these patients can continue to enjoy–coffee.

Sanka®Brand is 100% real coffee. But it is 97% caffeine-free. Each cup of Sanka®Brand Decaffeinated Coffee contains just a fraction of the caffeine found in an equivalent cup of regular coffee, so it does not exacerbate your patient's underlying condition.

And because Sanka®Brand tastes good, it aids patient compliance. What's more, i is available everywhere in instant, freeze-dried or ground-roast forms. It's even available at restaurants in convenient single-service packages. So your patient will have no problem maintaining your prescribed diet recommendation.

Non-stimulating Sanka®Brand is ideally suited to many special diets. And more physicians recommend it than all other brands of decaffeinated coffee combined.

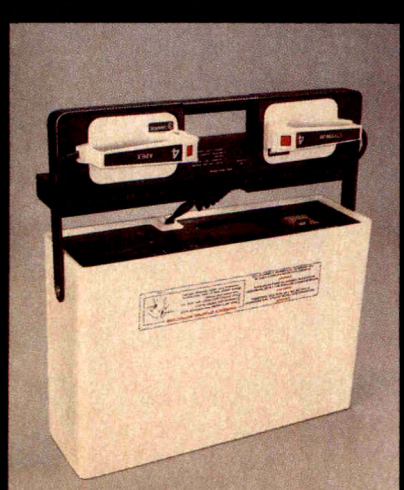
Air-Shields® Porta-Fib® III Defibrillator

Unmatched in taking charge of one of life's most critical moments



You can't afford to think twice about saving a life. So, you can't risk thinking twice about the operation of a defibrillator. Now, when every second counts, you can concentrate on the patient... not the equipment... with Air-Shields' action-ready Porta-Fib III Monitor/Defibrillator!

- clear, clean, concise control layout with unique combination handle/workstation
- defibrillator functions instantly visible on dedicated, boldly identified pushbuttons
- each emergency operating step clearly indicated in large numerical sequence for quick set-up – even with new users
- built-in annotating recorder and real-time/elapsed-time clock for complete documentation
- sealed membrane keypads and smooth high-impact plastic case, easy to clean and built for rugged, dependable service

For literature and a demo, call toll free 800-523-5756.

Lopressor®
metoprolol tartrate

An antihypertensive
beta-blocking agent

Tablets of 50 mg
Tablets of 100 mg

Prescribing Information

Brief Summary of Prescribing Information

Indications Lopressor is indicated in the management of hypertension. It may be used alone or in combination with other antihypertensive agents, especially thiazide-type diuretics.

Contraindications Lopressor is contraindicated in sinus bradycardia, heart block greater than first degree, cardiogenic shock, and overt cardiac failure (see **Warnings**).

Warnings ***Cardiac Failure:*** Sympathetic stimulation is a vital component supporting circulatory function in congestive heart failure, and beta blockade carries the potential hazard of further depressing myocardial contractility and precipitating more severe failure. In hypertensive patients who have congestive heart failure controlled by digitalis and diuretics, Lopressor should be administered cautiously. Both digitalis and metoprolol slow AV conduction.

In Patients Without a History of Cardiac Failure continued depression of the myocardium with beta-blocking agents over a period of time can, in some cases, lead to cardiac failure. At the first sign or symptom of impending cardiac failure, patients should be fully digitalized and/or be given a diuretic, and the response observed closely. If cardiac failure continues, despite adequate digitalization and diuretic, Lopressor therapy should be withdrawn.

Ischemic Heart Disease: Following abrupt cessation of therapy with certain beta-blocking agents, exacerbations of angina pectoris and, in some cases, myocardial infarction have been reported. Even in the absence of overt angina pectoris, when discontinuing therapy, Lopressor should not be withdrawn abruptly, and patients should be cautioned against interruption of therapy without the physician's advice.

Bronchospastic Diseases: **PATIENTS WITH BRONCHOSPASTIC DISEASES SHOULD IN GENERAL NOT RECEIVE BETA BLOCKERS. Because of its relative beta$_1$ selectivity, however, Lopressor may be used with caution in patients with bronchospastic disease who do not respond to, or cannot tolerate, other antihypertensive treatment. Since beta$_1$ selectivity is not absolute, a beta$_2$-stimulating agent should be administered concomitantly and the lowest possible dose of metoprolol should be used. It may be prudent initially to administer metoprolol in smaller doses three times daily, instead of larger doses two times daily, to avoid the higher plasma levels associated with the longer dosing interval. (See Dosage and Administration.)**

Major Surgery: The necessity or desirability of withdrawal of beta-blocking therapy prior to major surgery is controversial. It should be noted, however, that the impaired ability of the heart to respond to reflex adrenergic stimuli may augment the risks of general anesthesia and surgical procedures.

Metoprolol, like other beta blockers, is a competitive inhibitor of beta-receptor agonists and its effects can be reversed by administration of such agents, e.g., dobutamine or isoproterenol. However, such patients may be subject to protracted severe hypotension. Difficulty in restarting and maintaining the heart beat has also been reported with beta blockers.

Diabetes Mellitus: Beta-adrenergic blockade may mask symptoms of hypoglycemia (e.g., tachycardia) and may potentiate insulin-induced hypoglycemia. Lopressor should therefore be used with caution in diabetic patients, especially those with labile diabetes.

Thyrotoxicosis: Beta-adrenergic blockade may mask certain clinical signs (e.g., tachycardia) of hyperthyroidism. Patients suspected of developing thyrotoxicosis should be managed carefully to avoid abrupt withdrawal of beta blockade which might precipitate a thyroid storm.

Precautions ***Impaired Hepatic or Renal Function:*** The drug should be used with caution in patients with impaired hepatic or renal function.

Drug Interactions: Catecholamine-depleting drugs (e.g., reserpine) may have an additive effect when given with beta-blocking agents. Patients treated with Lopressor plus a catecholamine depletor should therefore be closely observed for evidence of hypotension and/or marked bradycardia which may produce vertigo, syncope, or postural hypotension.

Long-Term Animal Studies: Long-term studies in animals have been conducted to evaluate toxic effects and carcinogenic potential. In a one-year study in dogs, there was no evidence of drug-induced toxicity at or below oral doses of 105 mg/kg per day. Two-year studies in rats at three oral dosage levels of up to 800 mg/kg per day did not indicate an increase in the development of spontaneously occurring benign or malignant neoplasms of any type. The only histologic changes which appeared to be drug-related were an increased incidence of generally mild focal accumulation of foamy macrophages in pulmonary alveoli and a slight increase in biliary hyperplasia. Neither finding represents symptoms of a known disease entity in man. In a 21-month study in mice at three oral dose levels of up to 750 mg/kg per day, benign lung tumors (small adenomas) occurred more frequently in female mice receiving the highest dose than in untreated control animals. There was no increase in malignant lung tumors or total (benign plus malignant) lung tumors. The overall incidence of tumors or malignant tumors was also unaffected by metoprolol administration.

Usage In Pregnancy: Reproduction studies in animals did not reveal any evidence of impaired fertility or of teratogenic potential. There was evidence in the rat of increased postimplantation loss and decreased neonatal survival (threshold between 50 and 500 mg/kg). Distribution studies in mice confirm exposure of the fetus when metoprolol is administered to the pregnant animal. There are no well-controlled studies in pregnant women. Lopressor should be used in pregnant women only when clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Since most drugs are excreted in human milk, nursing should not be undertaken by mothers receiving metoprolol.

Usage in Children: Safety and effectiveness in children have not been established.

Adverse Reactions Most adverse effects have been mild and transient.

Central Nervous System: Tiredness and dizziness have occurred in about 10 of 100 patients. Depression was reported in about 5 of 100 patients. Headache, nightmares, and insomnia have also been reported but drug relationship is not clear.

Cardiovascular: Shortness of breath and bradycardia have occurred in approximately 3 of 100 patients. Cold extremities; arterial insufficiency, usually of the Raynaud type; palpitations and congestive heart failure have been reported. See **Contraindications**, **Warnings**, and **Precautions**.

Respiratory: Wheezing (bronchospasm) has been reported in less than 1 of 100 patients. See **Warnings**.

Gastrointestinal: Diarrhea has occurred in about 5 of 100 patients. Nausea, gastric pain, constipation, flatulence, and heartburn have been reported in 1 of 100 or less.

Allergic: Pruritus has occurred in less than 1 of 100 patients.

Miscellaneous: Peyronie's disease has been reported in less than 1 of 100,000 patients.

The oculomucocutaneous syndrome associated with the beta blocker practolol has not been reported with Lopressor during investigational use and foreign marketing experience.

Potential Adverse Effects: In addition, a variety of adverse effects not listed above have been reported with other beta-adrenergic blocking agents, and should be considered potential adverse effects of metoprolol.

Central Nervous System: Reversible mental depression progressing to catatonia; visual disturbances; hallucinations; an acute reversible syndrome characterized by disorientation for time and place, short-term memory loss, emotional lability, slightly clouded sensorium, and decreased performance on neuropsychometrics.

Cardiovascular: Intensification of AV block (see **Contraindications**).

Hematologic: Agranulocytosis, nonthrombocytopenic purpura, thrombocytopenic purpura.

Allergic: Erythematous rash, fever combined with aching and sore throat, laryngospasm and respiratory distress.

Miscellaneous: Reversible alopecia.

Clinical Laboratory Test Findings: Elevated blood urea levels in patients with severe heart disease, elevated serum transaminase, alkaline phosphatase, lactate dehydrogenase.

Dosage and Administration Dosage of Lopressor should be individualized. The usual initial dose is 100 mg daily in single or divided doses whether used alone or added to a diuretic. The dosage may be increased at weekly (or longer) intervals until optimum blood pressure reduction is achieved. In general, the maximum effect of any given dosage level will be apparent after one week of therapy. The effective dosage range is 100 to 450 mg per day. Dosages above 450 mg per day have not been studied. While once daily dosing is effective and can maintain a reduction in blood pressure throughout the day, lower doses (especially 100 mg) may not maintain a full effect at the end of the 24-hour period and larger or more frequent daily doses may be required. This can be evaluated by measuring blood pressure near the end of the dosing interval to determine whether satisfactory control is being maintained throughout the day. Beta$_1$ selectivity diminishes as dosage of Lopressor is increased.

This drug should be stored at controlled room temperature and protected from moisture.

How Supplied Tablets of 50 mg (capsule-shaped, scored, light red, film-coated) and 100 mg (capsule-shaped, scored, light blue, film-coated) are supplied in bottles of 100 and 1,000 and Unit Dose Packages of 100.

Store at controlled room temperature and protect from moisture.

Dispense in tight, light-resistant container (USP).

Consult complete product information before prescribing.

The next breakthrough in cardiac imaging.

Full-Spectrum Doppler®:
Because 2-D imaging alone is like watching a silent movie

Just as a silent movie can't tell it all, a silent 2-D image can't convey everything that's happening inside the heart

Now, the newest dimension in echocardiography only from Irex...2-D imaging, M-mode, plus FULL-SPECTRUM DOPPLER® for the noninvasive assessment of both hemodynamics and anatomy... a technique you can learn easily and quickly, with full training support from Irex.

In the unique Irex System, the Doppler audio signal is the key to getting the proper information from the Doppler examination...because it alone guides you to the optimum angle to flow for the most accurate measurement.

Once oriented correctly, pulsed Doppler provides the resolution needed for precise localization and selective sampling. CW Doppler is essential to detect the high flow velocities of most cardiac lesions and to assess the degree of obstruction. Only the Irex Phased Array Imaging System gives you *both* modes for the *complete* simultaneous 2-D/Doppler examination... plus a full-spectrum audio signal to *verify* results.

Hear FULL-SPECTRUM DOPPLER for yourself. Send for your audiocassette. Complete and return the coupon to hear the sound of a sound diagnosis.

The Pacekeeper™

For steady maintenance following cardioversion of supraventricular, ventricular, and atrial tachyarrhythmias

- Maintains normal sinus rhythm
- Full quinidine cardiodynamics
- Greater gastrointestinal tolerance than with quinidine sulfate*
- Convenient b.i.d. or t.i.d. dosage

*Bibliography available upon request.

CARDIOQUIN®
TABLETS
(quinidine polygalacturonate)

INDICATIONS AND USAGE: CARDIOQUIN Tablets are indicated as maintenance therapy after spontaneous and electrical conversion of atrial tachycardia, flutter or fibrillation and in the treatment of premature atrial and ventricular contractions, paroxysmal atrial tachycardia, paroxysmal A-V junctional rhythm, atrial flutter, paroxysmal atrial fibrillation, established atrial fibrillation when therapy is appropriate, and paroxysmal ventricular tachycardia when not associated with complete heartblock. CONTRAINDICATIONS: History of hypersensitivity to quinidine, complete A-V block, complete bundle branch block or other severe intraventricular conduction defects, myasthenia gravis, arrhythmias associated with digitalis toxicity. WARNINGS: In the treatment of atrial fibrillation with rapid ventricular response, use digitalis to control ventricular rate prior to administration of quinidine. In the treatment of atrial flutter, reversion to sinus rhythm may be preceded by progressive reduction in the degree of A-V block to a 1:1 ratio resulting in an extremely high ventricular rate. This potential hazard may be reduced by digitalization prior to administration of quinidine. *Potentially toxic digoxin plasma levels may occur when quinidine is administered concurrently. Consider reducing digoxin dosage and monitoring for digitalis toxicity.* Evidence of quinidine cardiotoxicity (increased P-R and Q-T intervals, 50% widening of QRS, and/or ventricular ectopic beats or tachycardia) mandates immediate discontinuation of the drug, and/or close clinical and electrocardiographic monitoring. NOTE: Quinidine effect is enhanced by potassium and reduced in the presence of hypokalemia. Quinidine should be used with extreme caution in the presence of incomplete A-V block, since complete block and asystole may result. Quinidine may cause abnormalities of rhythm in digitalized patients; therefore, it should be used with caution in the presence of digitalis intoxication. Caution is also called for in patients exhibiting renal, cardiac or hepatic insufficiency because of potential toxic accumulation of quinidine in plasma. PRECAUTIONS: A preliminary test dose of a single tablet of quinidine sulfate may be administered to determine if the patient has an idiosyncracy to quinidine. ECG monitoring and determination of plasma quinidine levels are recommended when doses greater than 2.5 g/day are administered. Periodic blood counts and liver and kidney function tests should be performed during long-term therapy.

DRUG INTERACTIONS OF QUINIDINE:

DRUG	EFFECT
With anticholinergic drugs	Additive vagolytic effect.
With cholinergic drugs	Antagonism of cholinergic effects.
With carbonic anhydrase inhibitors, sodium bicarbonate, thiazide diuretics	Alkalinization of urine resulting in decreas excretion of quinidine.
With coumarin anticoagulants	Reduction of clotting factor concentrations
With tubocurare, succinylcholine and decamethonium	Potentiation of neuromuscular blockade.
With phenothiazines and reserpine	Additive cardiac depressive effects.
With hepatic enzyme-inducing drugs (phenobarbital, phenytoin, rifampin)	Decreased plasma half-life of quinidine.
With digoxin	Increased plasma concentrations of digox (see WARNINGS).

PREGNANCY: The use of quinidine in pregnancy should be reserved only for those cases whe the benefits outweigh the possible hazards to the patient and fetus. NURSING MOTHERS: Th drug should be used with caution due to excretion of the quinidine in breast milk. ADVERS REACTIONS: SYMPTOMS OF CINCHONISM (ringing in the ears, nausea, headaches, and/ disturbed vision) may appear in sensitive patients after a single dose of the drug. GASTROINTES TINAL: Diarrhea, nausea, vomiting, abdominal pain. CARDIOVASCULAR: Widening of QR complex, cardiac asystole, ventricular ectopic beats, idioventricular rhythms (including ventricul tachycardia and fibrillation), paradoxical tachycardia, arterial embolism, and hypotension. HEMA TOLOGIC: Acute hemolytic anemia, hypoprothrombinemia, thrombocytopenic purpura, agranul cytosis. CNS: Headache, fever, vertigo, apprehension, excitement, confusion, delirium, ar syncope, disturbed hearing (tinnitus, decreased auditory acuity), disturbed vision (mydriasi blurred vision, disturbed color perception, reduced vision field, photophobia, diplopia, nig blindness, scotomata), optic neuritis. DERMATOLOGIC: Rash, cutaneous flushing with intens

SYMPOSIUM ON THE PHYSIOLOGY AND PATHOLOGY OF THE CORONARY CIRCULATION AND CORONARY HEART DISEASE.
Proceedings of the 6th Triennial Conference
of the National Heart Foundation of Australia

David T. Kelly, Guest Editor

Preface

DAVID T. KELLY, MB, FRACP

The National Heart Foundation of Australia sponsors a conference every 3 years. Formerly, these meetings were oriented toward a basic bioscience theme and attracted cardiovascular researchers rather than practicing cardiologists.

This 6th triennial conference examined the physiologic and pathologic aspects of the coronary circulation and coronary heart disease. This topic was chosen to provide a forum whereby scientists and practicing cardiologists could discuss areas of research in coronary heart disease and promulgate its importance.

The National Heart Foundation of Australia is a major sponsor of cardiovascular research in Australia. The money for this is raised by voluntary contributions from a public that is ever-increasingly aware of the major effects of coronary disease on its way of life and, indeed, life itself. Unfortunately, there is a paucity of research in coronary disease in Australia. A major aim of this conference was to highlight the areas of research and emphasize that it should be actively promoted in Australia.

Prostanoid metabolism is of ever-increasing importance in the pathophysiology of coronary disease, especially relative to coronary vasomotor changes and arterial thrombosis. Both thrombosis and spasm were discussed extensively on the second day of the meeting, as were the current knowledge of prostanoids on the cardiovascular system and vasospasm.

Much of the clinical research in coronary disease is now in the assessment and management of the patient with acute myocardial infarction. This topic and the results of intracoronary thrombolysis in acute infarction were discussed on the last day of the conference, as was the impact that both beta blockade and calcium antagonist therapy have made on management in myocardial infarction and angina.

A conference on coronary heart disease would be incomplete without mention of coronary artery surgery because of its influence in patient management and in the broader social implications of delivery of health care. In Australia all patients who have coronary artery surgery are registered and the results are analyzed by a committee of the National Heart Foundation. Such data on surgical trends for a whole country is difficult to obtain, and this unique experience is presented.

Atherosclerosis—Relationship to Coronary Blood Flow

ROBERT W. WISSLER, MD, PhD, and DRAGOSLAVA VESSELINOVITCH, DVM, MS

Human atherosclerotic plaques in coronary arteries consist of a variable mixture of lipids, cells and fiber proteins synthesized by the cells. The 2 major space-occupying components of the advanced lesions, which together obstruct the lumen, are the fibrous cap and the necrotic core from which the lesions derive their name. The smooth muscle cells, which make up most cells of the plaque, including the fibrous caps, are produced by migration from the media as well as by proliferation of these cells in the intima. The lipids, mostly supplied by circulating lipoproteins, are present not only in the atheromatous acellular core, but also in the cytoplasm of the cells of the lesion and extracellularly, often attached to 1 or more constituents of the fibrous matrix of the plaque (collagen, elastin and proteoglycans).

In both human and rhesus monkey coronary arteries, the lumen becomes more stenotic as the plaque becomes larger and enlarges as the plaque becomes smaller in response to lipid-lowering therapy. Recent studies in other nonhuman primate models of advanced atherosclerosis have questioned the influence of the plaque lesion on coronary blood flow. For example, in the cynomolgus species of macaque (*M. fascicularis*), depending on how the plaques are induced, the artery lumens may dilate as the plaques become larger because the outside diameters of the arteries increase. Furthermore some diseased arteries are found to stenose further when the animals with advanced coronary plaques are treated by measures that substantially reduce the lipids in the plaques.

Questions now being studied in several animal models and in human arteries include the relative influence of the degree of medial involvement, of lesion cell types, and of lesion circumferential localization (concentric versus eccentric) on these paradoxical phenomena.

Coronary artery atherosclerosis in humans is mostly a disease of the proximal 6 to 8 cm of the major coronary arteries. The lesions, which usually present as intimal plaques, consist of a variable mixture of lipids (including cholesterol and cholesteryl esters), cells and fiber proteins synthesized by the cells. The 2 major space-occupying components of the fully developed plaque, which together can lead to severe stenosis of the lumens of these arteries, are the fibrous cap and the necrotic atheromatous core from which the lesions derive their name (Fig. 1).

The smooth muscle cells, which make up most cells of the human plaque including the fibrous cap, are presumably the product of immigration of cells from the media, accompanied or followed by excessive proliferation (mitosis) of these cells in the intima (Fig. 2). The lipid-cholesterol mixture appears to be mostly supplied by circulating lipoproteins that traverse the endothelial "barrier" and are deposited. This cholesteryl ester-rich lipid is found not only in the atheromatous acellular core, but also in the cytoplasm of the smooth muscle cells, and to a variable extent in macrophages and extracellularly, often attached to 1 or more constituents of the fibrous cap (collagen, elastin or proteoglycans). The fiber proteins of the plaque are largely the product of these proliferated smooth muscle cells.

The space-occupying features of the growing plaque which result in stenosis, are responsible for much of the decrease in coronary blood flow that leads to ischemic heart disease. Nevertheless, many of the acute catastrophic episodes that we call "heart attacks" are triggered by the severe coronary plaques that are often ulcerated or that present a ruptured or torn fibrous cap (Fig. 3). This, in turn, promotes mural or obturating thrombosis or promotes spasm of the major coronary artery superimposed upon or alongside a major plaque that is ulcerated.

The forces that favor occlusion or promote fatal arrhythmias or classic myocardial infarction are opposed

From the Department of Pathology and the Specialized Center of Research on Atherosclerosis, University of Chicago, Pritzker School of Medicine, Chicago, Illinois. This study was supported in part by Grants HL15062 and HL17648 from the National Heart, Lung, and Blood Institute, National Institutes of Health, Bethesda, Maryland and by the University of Chicago's Cardiovascular Research Foundation.

Address for reprints: Robert W. Wissler, PhD, MD, University of Chicago, Department of Pathology, Box 414, 950 E. 59th Street, Chicago, Illinois 60637.

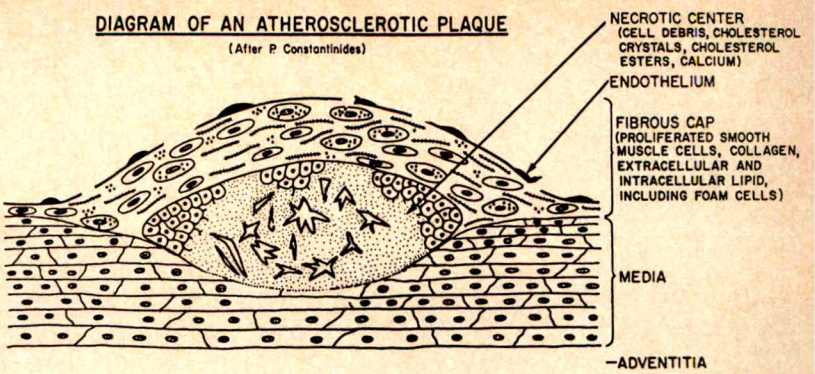

FIGURE 1. The major components of an advanced atherosclerotic plaque, including the grumous necrotic center from which the lesion derives its name and the fibrous cap made up largely of lipid-filled smooth muscle cells and fiber proteins produced by these cells, mainly collagen and elastin. The evidence of injured endothelium is a common feature of the advanced plaque.

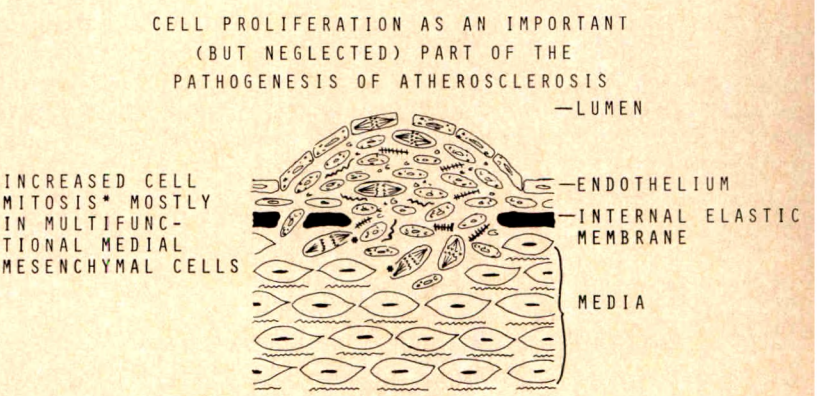

FIGURE 2. Arterial smooth muscle cell migration (from the underlying media) and active proliferation in both the intima and the media as important components of atherogenesis in human and nonhuman primate atherogenesis. LDL = low-density lipoprotein. Modified from Wissler RW. In: Homburger F, ed. Comparative Pathology of the Heart. Basel: S. Karger, 1974:10–31.

to a variable extent, by coronary artery collaterals[1] and by dilation of severely diseased arteries.[2] Weakening of the media and enlargement of the entire circumference counteract stenosis, as reflected by morphometric evaluation of the external elastic membrane.

The stenosing tendencies of the plaque are also strongly opposed in most humanoid animal models, and probably in humans with advanced disease as well, by an effective set of reactions that occur when the lipid levels in the blood are lowered to levels often observed in most adults in populations where atherosclerosis usually does not progress and ischemic heart disease is rare. This evidence of decrease in lesion size (regression), healing of endothelium and remodeling of the fibrous cap has been well documented in numerous quantitative studies of regression of advanced atherosclerosis in macaques, dogs and swine.[3–8]

This presentation documents and evaluates some recent human clinical-pathologic and experimental pathophysiologic data that support the concept of these opposing forces involved in progression, healing and regression.

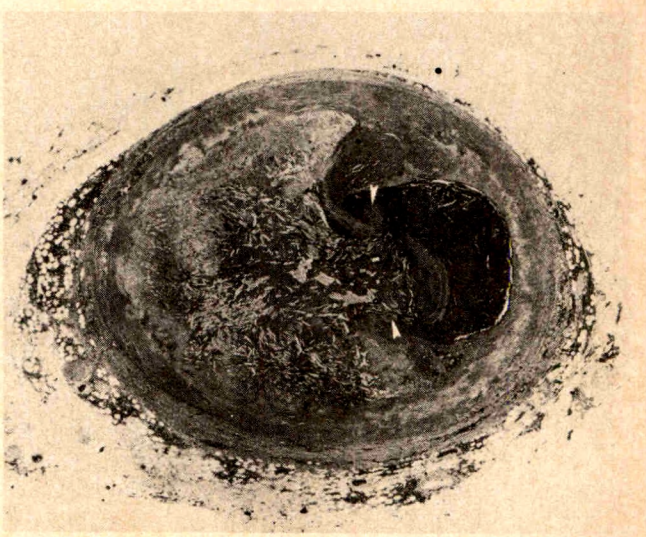

FIGURE 3. Photomicrograph from an occluded coronary artery in which the thrombosis appears to be directly related to a ruptured fibrous cap over a very severely diseased plaque, which has a large necrotic, cholesterol-rich core. Reproduced from Buja LM, Willerson JT. Am J Cardiol 1981;47:343–356, with permission of the publisher.

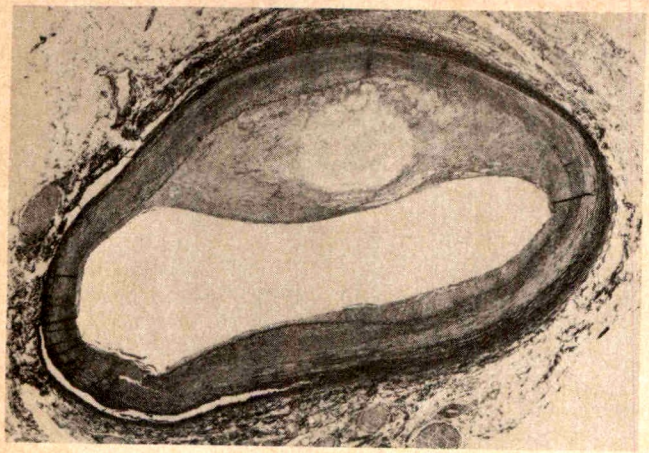

FIGURE 4. Coronary artery plaque from a 54-year-old man who was found to have subendocardial myocardial necrosis when he died, about 12 hours after acute onset of chest pain. The lesion, a prototype of many observed at autopsy and probably not detected by angiography, is characterized by a thin, loose, fibrous cap and a proportionately larger necrotic center.[9]

New Data on Plaque Progression

Roberts[9] studied severe atherosclerotic plaques from human autopsies and recognized that the mass of the plaque may not be as important as the relative quantities of components in triggering a clinical event. For example, many relatively small, eccentric plaques, each with a very lipid-rich center and a very thick fibrous cap, have been shown that could not be detected with angiography. These soft and "florid" plaques are dangerous because of their propensity to "fibrous" cap rupture and platelet adherence, resulting in thrombosis or coronary spasm (Fig. 4).

Roberts[10] proposed patterns of stenosis and described eccentric and concentric plaques. Two examples of advanced concentric and eccentric coronary lesions in the human are shown in Figure 5.

Our observations in rhesus monkeys and cynomolgus monkeys using identical atherogenic rations in our laboratory have suggested a new interpretation of eccentric versus concentric lesions (Fig. 6).

The cynomolgus monkey regularly develops co centric coronary lesions, but the same diet fed to th rhesus monkey (Fig. 6) almost exclusively produc eccentric coronary lesions. These cynomolgus lesio often display a large proportion of mononuclear cell many of which are converted to foam cells. The foa cells are not only intimal but often become concentr cally transmural with extensive destruction of th media. In numerous instances, the adventitia is als extensively involved. These atheromatous lesions r semble the transmural lipid-rich lesions seen in som patients with incompatible human heart transplants c those produced experimentally by Alonso et al[11] i homologously transplanted animals and Minick e al[12,13] in rabbits with serum sickness (both groups re ceived an atherogenic ration). These lesions resembl those seen in hypercholesterolemic subjects who als have immune complex panarteritis.

When findings in rhesus and cynomolgus monkey were compared with those from our laboratory, over 80 of cynomolgus monkeys had definite evidence or ci culating Ag-Ab complexes, but rhesus monkeys di not.

We believe that this widespread concentric and ofte highly destructive lesion in cynomolgus monkeys i different from most coronary lesions in humans an may explain why regression is uncommon.[8,14,15] Othe investigators have observed different regression pat terns in cynomolgus lesions under conditions tha consistently lead to regression of advanced atheroscle rosis in the rhesus species of macaques (*Macaca mu latta*). These transmural lesions, with their smolderin medial inflammation, form scars that constrict whe they lose their lipids. Malinow et al[16] reported an ex ception. Using a less atherogenic ration and a short in duction, these workers reported substantial regressio resulting from incorporation of either alfalfa meal o cholestyramine in the slightly modified atherogeni ration.

Bond et al[2] reported that this lesion produces mor dilatation of the artery, as measured by the increase ir diameter or circumference of the internal elasti membranes during induction, than they observed ir rhesus monkeys (Table I) and that this may alter cor onary flow. Vesselinovitch and Wissler[17] showed a

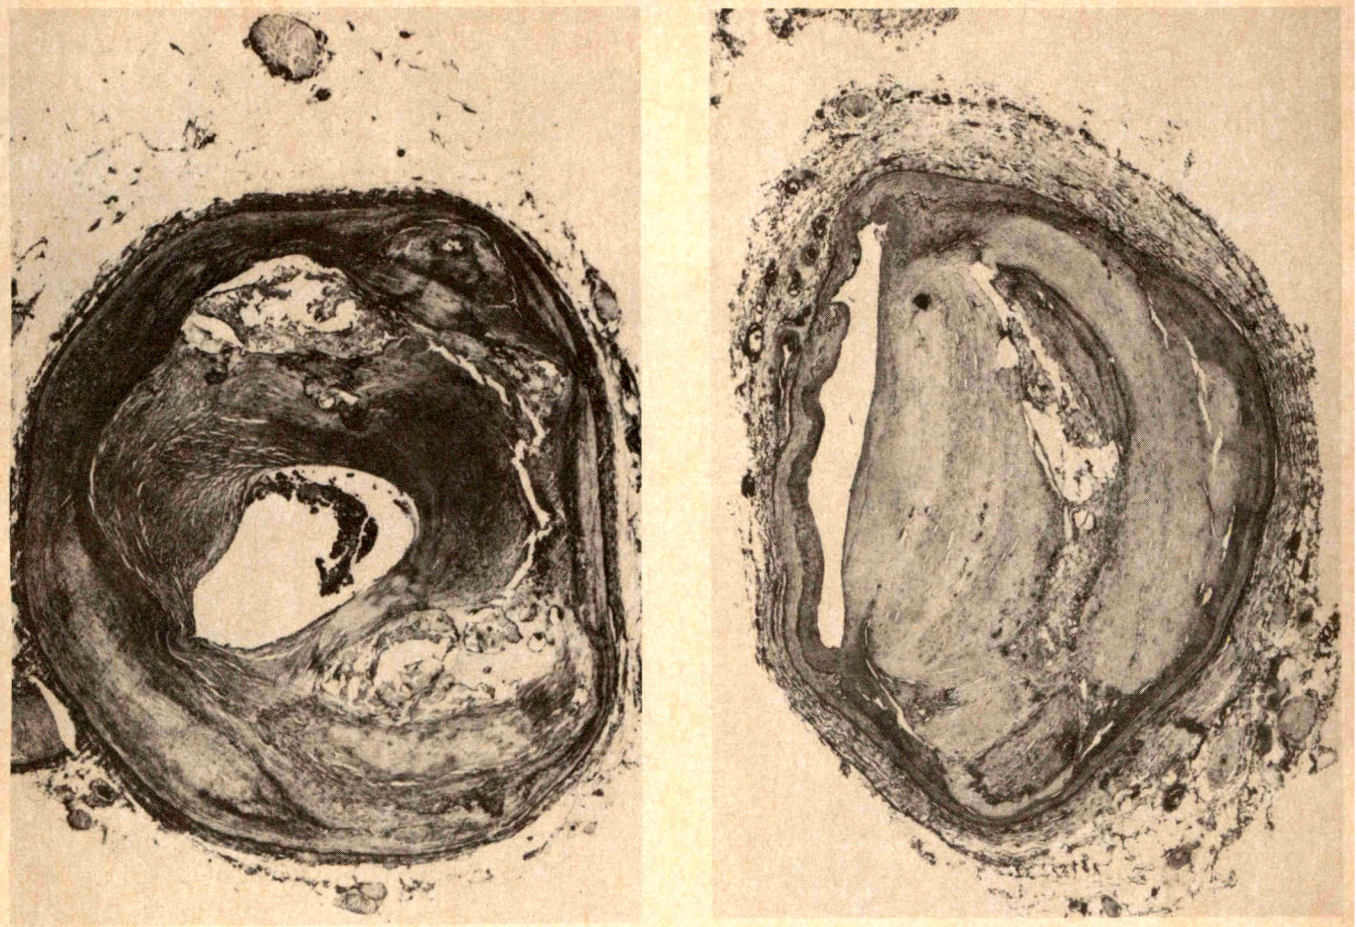

FIGURE 5. Photomicrographs of concentric and eccentric lesions in coronary arteries, which illustrate much more medial involvement and medial degeneration and atrophy in the concentric lesion. Note the intact media opposite the eccentric lesion. Reproduced from Roberts[9] with permission of the publisher.

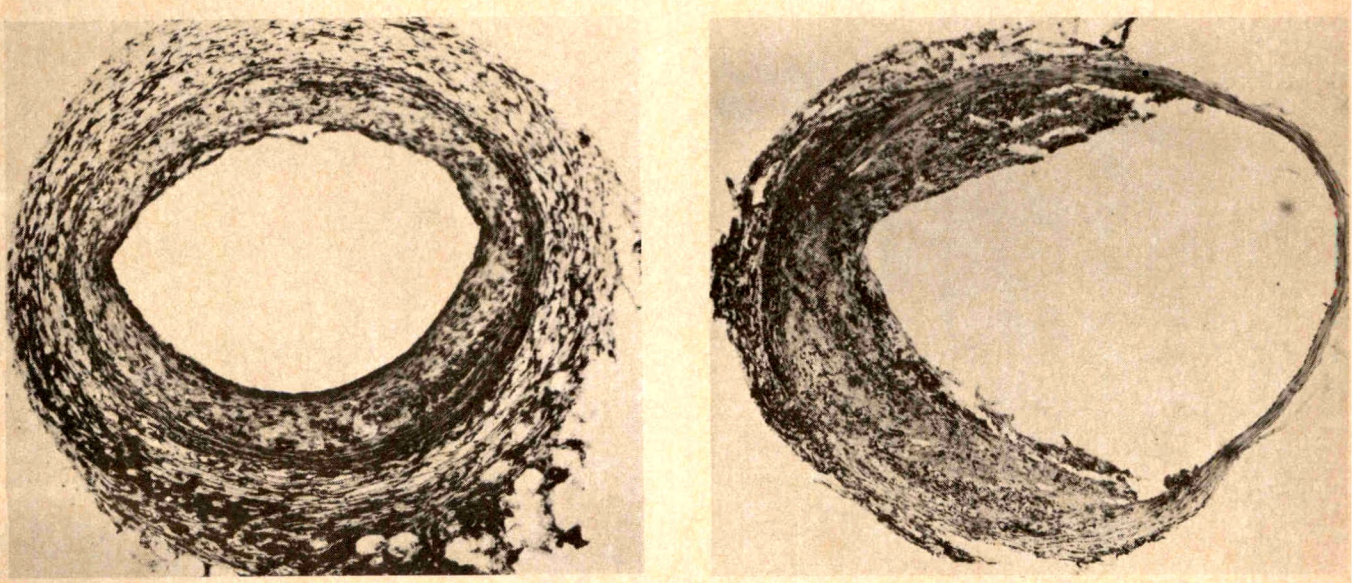

FIGURE 6. Advanced plaques from a recent experiment.[17] **Left,** lesion stained with a fat stain, is a typical concentric lesion, with abundant destructive medial involvement and extensive adventitial foam cell infiltration. **Right,** a typical rhesus lesion with an advanced eccentric plaque showing a necrotic center and very little damage to the arterial medial musculature except in small focal areas.

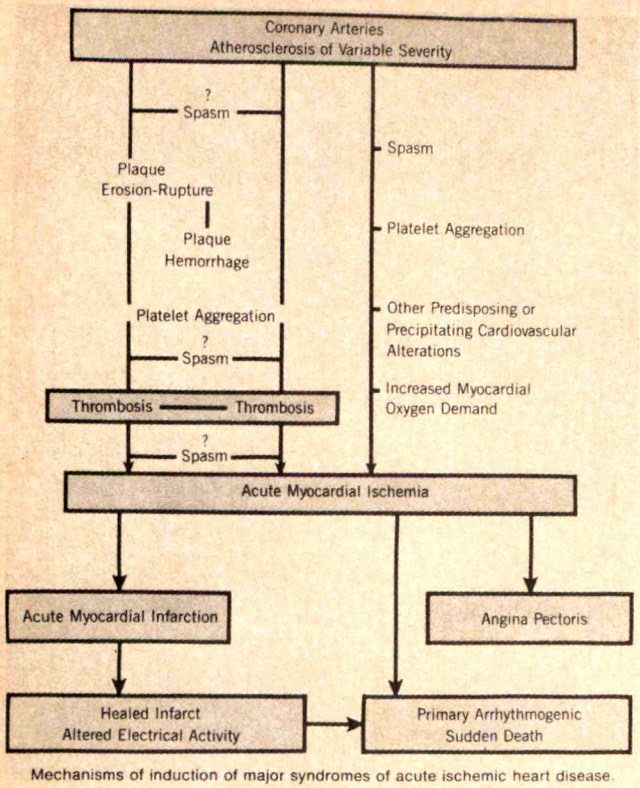

FIGURE 7. The two types of pathogenetic sequences, each of which may account for about half of the heart attacks in the United States. Reproduced from Buja et al[18] with permission of the publisher.

definite arterial dilatation in cynomolgus monkeys but no change as the lumen filled in with plaque in the adult male rhesus monkeys. These observations may be clinically important because concentric coronary lesions, with extensive medial destruction or atrophy, are occasionally seen in humans, and may be detected by noninvasive techniques and differentiated from the usual eccentric intimal coronary plaque.

Concentric transmural medial lesions should be associated with greater dilation of lumens during atherogenesis[2] and less decrease in stenosis during regression.[14,15,17] The concentric lesion may be less likely to be associated with vasomotor change.[18] The more usual eccentric lesions would not increase the outside diameter of the artery during progression, except that those which accompany growth would be associated both with a more effective regression with less fibrous replacement of the media and with restoration of the original lumen. The intact media away from the plaque may develop spasm due to the greater preservation and availability of smooth muscle cells.

A recent review[18] suggests that a disrupted intimal over a soft (but not necessarily angiographically visible) plaque may be important in the pathogenesis of coronary spasm. This suggests a dual pathogenesis of clinical event (Fig. 7), both associated with severe atherosclerosis, 1 associated with spasm and 1 with thrombosis.

Figure 7 illustrates the probable pathogenetic sequence[18] and shows agreement with the findings of other investigators.[19,20]

Increased levels of catecholamines during stressful episodes or those liberated from platelets spread over ulcerated or partially denuded atherosclerotic plaques may trigger vasomotor changes. Coronary spasm, which could be the missing link of the chain, is such a common cause of acute heart attacks due to sudden onset of arrhythmia.

New Data on Plaque Regression

Atherosclerosis in humans[21,22] and in the rhesus monkey model[23,24] can be partially reversed; studies suggest that a small decrease in an advanced obstructive plaque could greatly increase coronary blood flow. In chronic hypercholesterolemic animals, when serum cholesterol level is lowered the damaged endothelium is repaired. The atherosclerotic plaques may not cause platelets to stick and release vasoactive amines.[25,26] The changes that occur in experimental studies of regression in the rhesus monkey are shown in Figure 8.[27] In humans, Barndt et al[28] documented that regression occurs in patients who have lowered their serum cholesterol levels substantially in contrast to those who could not.

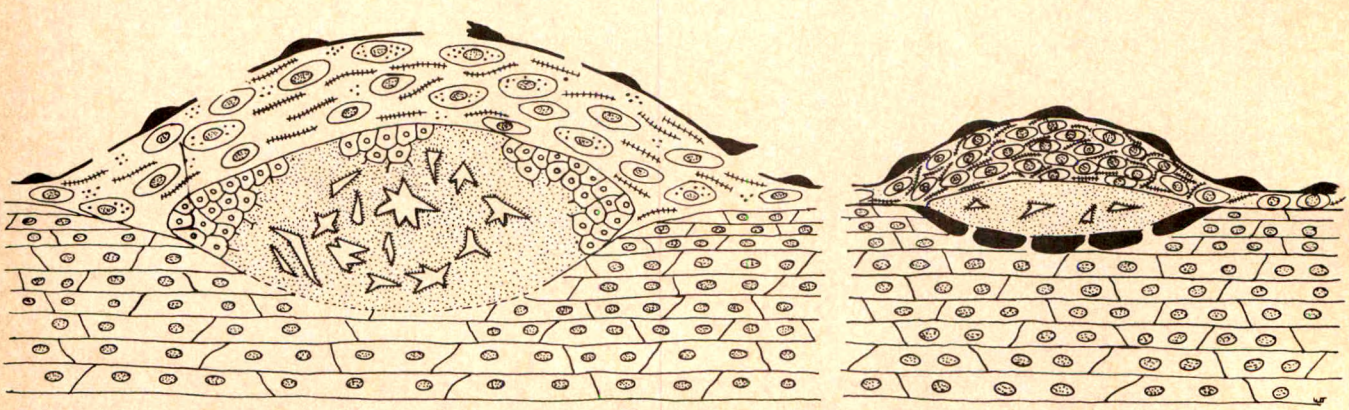

FIGURE 8. The major changes observed in quantitative studies of plaque regression in several species of experimental animals. **Left,** a typical advanced plaque. The main features usually seen in this process (**right**) are healing of endothelium, a substantial decrease in size and lipid cholesterol content of the necrotic center, a marked reduction in intra- and extracellular lipid in the fibrous cap, and condensation of the fiber proteins in this part of the plaque; as a result of these changes, the plaque size is reduced. Reproduced from Barndt et al[28] with permission of the publisher.

Similarly, Bevans et al[3] reported that sequential coronary arteriograms may show regression of atherosclerosis a year or 2 after partial ileal bypass therapy when patients have significantly lowered serum cholesterol and low-density lipoprotein values.

Our present knowledge of the mechanisms by which coronary atherosclerosis produces its effect on coronary blood flow suggests that regression of plaque size would occur in those persons who have a sustained lowering of their serum lipid levels.

Future Prospects

In the animal models such as *Macaca mulatta*, whose advanced plaques resemble human atherosclerosis most closely, the same type of stenosing lesions as those in humans are found and various therapeutic regimens can be tested. Effects of therapy over time on coronary flow and lesions can be studied. In the experimental model, these results can be validated in vivo by highly quantitative morphometric observations made in postmortem specimens.

The large, cumbersome, often complex mass clinical trials in humans, with their end points of mortality or myocardial infarction, can be replaced by evaluation of intervention using direct noninvasive imaging and Doppler flow techniques. These can be monitored by quantitative morphometric techniques applied to the human autopsy specimens of the same coronary arteries. These approaches are being explored in both experimental animals and human carotid and femoral arteries.[29]

Local Factors Controlling Coronary Circulation

DAVID E. L. WILCKEN, MD

Mechanical, metabolic, anatomic and, possibly, myogenic factors contribute to the local regulation of coronary blood flow. The hindrance to flow produced by systole can easily be quantitated, but the measurement of diastolic pressure-flow relations in the different layers of myocardium poses problems. The coronary circulation is an autoregulated vascular bed, and failure of autoregulation produces subendocardial ischemia. Flow is almost entirely diastolic and the available evidence suggests that variations in diastolic extravascular pressure across the myocardium result in a series of waterfall effects; these extravascular pressures are highest in the endocardium and decrease progressively toward the epicardium. This hypothesis would explain subendocardial ischemia with reduced diastolic perfusion pressures when the coronary circulation is maximally vasodilated.

Metabolic factors produce large changes in coronary flow and flexibility in adjusting oxygen supply to need. Present data suggest an important role for adenosine as a vasodilator mediator. Considering the importance of metabolic vasodilatation for normal cardiac function, a unitary theory of regulation with a single vasodilator would lack built-in safety factors and flexibility; it is unlikely that there is a single mediator for every kind of physiologic coronary vasodilatation. Evidence is accumulating for interrelations between naturally occurring coronary vasodilators, with important links provided by prostaglandins, and for intrinsic changes in vascular smooth muscle function contributing to postocclusion hyperemia.

Changes in vascular smooth muscle function alter flow within limits dictated by coronary anatomy. The wide anatomic variation between individual subjects is consistent with the importance of genetic factors in determining the anatomic characteristics of the coronary vascular tree, and the effect these will have on myocardial perfusion, particularly in pathophysiologic states.

Three basic phenomena determine resistance to blood flow in the coronary circulation: the mechanical effect of the beating heart, the contractile activity of the smooth muscle cells in the walls of the coronary vessels, and the anatomy of the coronary vasculature and its collateral circulation. The first produces a mechanically determined hindrance to coronary flow unrelated to any intrinsic control of coronary conductance; the second is under the control of both the cardiac nerves and local metabolic processes of the heart. In the third, the differences between individuals and between species are presumably genetically determined, but accentuated by varying myocardial oxygen requirements and the presence of myocardial ischemia. This study examines some recent developments, touching upon each of these 3 determinants of coronary vascular resistance or its reciprocal conductance.

Extravascular Coronary Resistance

Downey[1] reviewed changes in coronary conductance the heart itself produces by compressing coronary vessels during systole, and thereby increasing resistance to flow. Sabiston and Gregg[2] established that this is indeed the case beyond doubt 25 years ago when they measured right and left coronary artery flow in dogs at constant perfusion pressure before and after temporary asystole produced by vagal stimulation; with the onset of asystole there was always a dramatic increase in coronary blood flow. They showed that in the normal heart, one third to one half of total coronary resistance is extravascular in origin, and that this is almost certainly due to systolic compression of coronary vessels. It is difficult to obtain absolute values for tissue pressure during systole so as to quantitate transmural extravascular systolic forces. Nevertheless, the findings in these early experiments, and many related ones subsequently, provide an adequate explanation for left

ventricular coronary flow being almost entirely a diastolic phenomenon. Indeed, recent data suggest that flow recorded in systole (about 20% of the total) remains in superficial distensible conducting vessels and that subendocardial flow is entirely diastolic.[3,4] Since the subendocardial region of the left ventricle is the area most vulnerable to ischemic damage, an important immediate question is: What effects do the mechanical events of the cardiac cycle have on diastolic perfusion?

Hoffman and co-workers[5,6] approached this in the following way: they proposed that flow per beat is in proportion to the diastolic pressure-time index (DPTI), defined as the area between the ventricular pressure and the aortic pressure during the diastolic period; and that the metabolic requirements per beat were dictated by the area under the systolic pressure-time index (SPTI) as described by Sarnoff et al.[7] The ratio of DPTI/SPTI was then used as an index of the supply-demand status of the myocardium. They plotted the DPTI/SPTI against measurements of regional myocardial blood flow, determined by the distribution of injected radioactive microspheres, in experiments that reproduced the hemodynamic changes found in clinical situations. The results are summarized in Figure 1. This figure shows that there is normally an even distribution of flow between epicardium and endocardium, the ratio DPTI/SPTI is normally approximately 1, and interventions that lower the ratio to about 0.5 result in a progressive reduction in endocardial flow relative to epicardial flow.

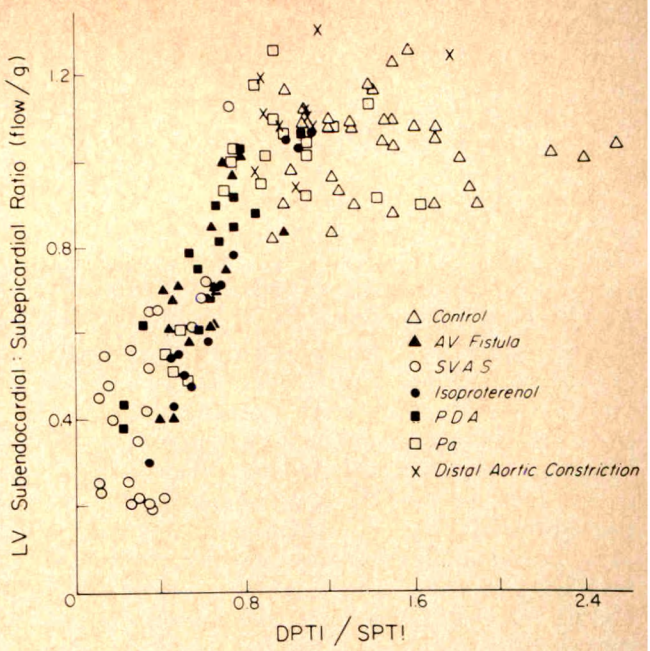

FIGURE 1. The reaction between DPTI:SPTI (ratio of diastolic pressure-time index to systolic pressure-time index) to subendocardial: subepicardial flow in anesthetized dogs in different experiments that mimicked clinical situations (see text). Subendocardial flow decreases relative to subepicardial flow with pressure ratios below about 0.6. AV = arteriovenous; Pa = pacing; PDA = patent ductus arteriosus; SVAS = supravalvular aortic stenosis. Reproduced from Hoffman[6] with permission of the publisher.

The coronary circulation is an autoregulated vascular bed so that, for a given myocardial oxygen demand, coronary blood flow remains relatively constant over a wide range of imposed perfusion pressures.[8,9] The experiments of Hoffman et al[5,6] suggest that autoregulation extends into the various layers of the left ventricle, which have different systolic, and presumably diastolic, tissue pressures, and that autoregulation persists despite major pressure and flow changes. It follows that there are powerful mechanisms operating in the myocardium to maintain even transmural perfusion. This is well illustrated by the experiments in dogs by Rouleau et al,[10] who kept myocardial oxygen requirements constant and determined the effect on regional myocardial blood flow of altering coronary perfusion pressure. Even transmural perfusion was maintained over a wide range of pressures, but when a breakdown in transmural autoregulation did occur, it always resulted in subendocardial ischemia. Subendocardial ischemia occurs when autoregulating mechanisms produce maximal coronary vasodilatation so that subendocardial flow becomes entirely dependent upon perfusion pressure;[10] a further decrease in perfusion pressure then results in subendocardial ischemia.

The reasons for subendocardial vulnerability to ischemia are obviously important. Two major reviews have considered this question recently.[1,11] A superficial view might be that as the subendocardium is perfused only in diastole, it is simply at the end of the line for a flow system perfusing from the epicardial surface of the heart to the endocardium. Yet there is good evidence that endocardial conductance is greater than that for the epicardium,[10,12,13] and there is also mounting evidence for the importance of waterfall effects occurring in the coronary circulation and influencing diastolic perfusion.

The waterfall hypothesis was suggested by Holt[14] and has been shown to be important in other regional circulations, particularly in the lung.[15] If, as seems likely, small coronary veins act like collapsible tubes passing through relatively rigid heart muscle, conditions in the myocardium are analogous to those produced by a Starling resistor.[16] The difference between diastolic inflow pressure and diastolic extravascular or tissue pressure will determine diastolic flow if the tissue pressure is higher than that in the right atrium. Downstream pressure will not affect diastolic flow as long as it is lower than the diastolic extravascular tissue pressure compressing collapsible upstream vessels. Under these circumstances, if inflow pressure is progressively lowered, flow will stop when inflow and tissue extravascular pressures are the same. Thus, if there are diastolic waterfall effects in the myocardium, pressure at zero flow should equal tissue extravascular pressure. This consideration excludes contributions from inertial forces and the capacitance of the vessels, but these contributions are likely to be small.[1,11]

Bellamy[17] examined pressure-flow relations in conscious dogs at very slow heart rates. He found linear pressure-flow relationships during long diastolic pauses under resting conditions, with a pressure intercept of

about 50 mm Hg. With maximal vasodilatation, the intercept was 15 to 20 mm Hg. This suggests that the pressure intercept at zero flow is affected by vascular tone and that during maximal vasodilatation this pressure may represent the myocardial extravascular pressure.

Reexamination of pressure-flow curves determined in this laboratory in chronically conscious dogs entirely confirmed Bellamy's results in relation both to the linearity of the pressure-flow relationships and the magnitude of the pressure intercept, both under resting conditions and during maximal coronary vasodilatation (Wilcken DEL, unpublished data). Distal coronary artery diastolic pressures after circumflex coronary artery occlusions have been of the same magnitude. In conscious humans, distal coronary artery diastolic pressures at zero flow, determined during complete occlusion of the left anterior descending coronary artery at percutaneous transluminal angioplasty in this institution, have also consistently shown diastolic values of 10 to 20 mm Hg (McCredie RM, personal communication). Although these distal pressures may, in some instances, be influenced by collateral flow, it is nevertheless important to note that in >100 occlusions performed in this institution in dogs and man, distal coronary artery pressures have always been of that order.

The relevance of the waterfall hypothesis to subendocardial ischemia is supported by the finding of Rouleau et al[10] of a higher diastolic pressure intercept for the endocardium than for the epicardium, when intercepts were obtained by extrapolation of linear pressure-flow curves from different layers of the dog myocardium. This same group has provided evidence for a waterfall effect occurring in the coronary sinus.[18] These data suggest that when there is maximal coronary vasodilatation, and flow to the subendocardium then depends only on coronary driving pressure, flow to the endocardium will decrease first because diastolic coronary extravascular pressures are higher there than in the middle and subepicardial layers; therefore, for a given diastolic coronary perfusing pressure, the epicardial driving pressure will be greater than that for the endocardium and, under conditions of maximal vasodilatation, the decrease in subendocardial driving pressure will inevitably result in lower endocardial flow.

Coronary Vascular Smooth Muscle Activity and Conductance

Although extravascular factors are responsible for up to 50% of the hindrance to flow and are largely systolic, contributions from metabolic, neural and, possibly, myogenic factors account for the remainder by changing coronary vascular smooth muscle activity. They introduce flexibility into the system by permitting flow to vary widely in relation to physiologic demands. It may increase 6- or 7-fold above resting levels; there is little doubt that metabolic factors are the most potent mediators of these responses, which are essential for increased oxygen delivery, because of the high oxygen extraction at rest in the coronary circulation (>50%).[9]

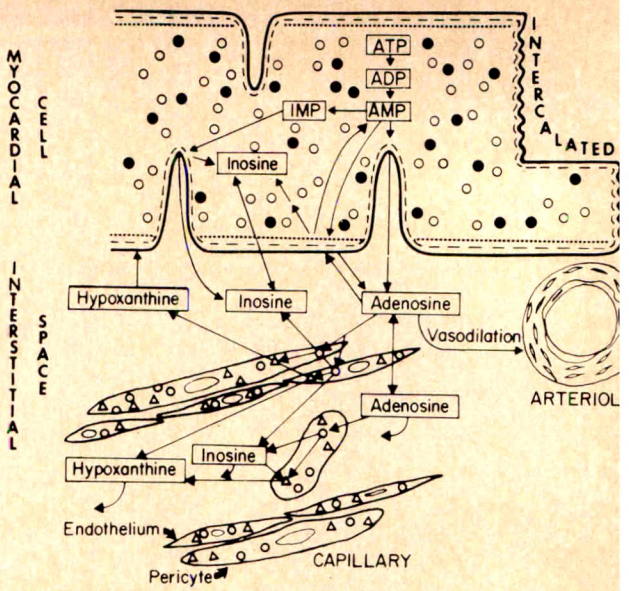

FIGURE 2. The adenosine hypothesis. AMP is formed from the brea down of ATP in the myocardial cell and is dephosphorylated at the ce membrane by 5′-nucleotidase. Adenosine moves into the interstiti space to act on vascular smooth muscle producing vasodilatation reenters the myocardial cell. Any adenosine moving into the bloc stream is deaminated to inosine and hypoxanthine. Reproduced fro Berne and Rubio[9] with permission of the publisher.

Metabolic Regulation

The relationship between myocardial metabolic ac tivity and coronary vessel tone has been reviewed au thoritatively by Parratt.[19] There is a linear relationshi between coronary blood flow and myocardial oxyge consumption[9,19] and a hyperbolic relationship wit coronary venous oxygen content (reflecting myocardia oxygen partial pressure), sharp increases in flow oc curring when coronary venous oxygen content fall below 5 ml/100 ml.[20] Although oxygen itself might hav a direct effect on vascular smooth muscle, it is unlikel that a change in coronary perivascular oxygen tensio alone is the principal mechanism for metabolically in duced coronary vasodilatation. For example, Broadley[2] perfused 2 guinea pig isolated hearts in series with physiologic solution and reoxygenated the effluent fron the donor heart before it reached the recipient heart This latter heart had been pretreated with histamin receptor and adrenoceptor-blocking drugs. Epineph rine, isoproterenol or histamine given to the donor hear produced coronary vasodilatation in the recipient heart so, too, did tachycardia induced in the donor heart by electrical pacing and hypoxia. There was, therefore myocardial release of a stable vasodilator substance o substances producing vasodilatation in the fully oxy genated recipient heart.

A number of vasoactive substances link coronary blood flow to the metabolic requirements of the heart the evidence for and against the various putative cou pling agents has been extensively reviewed.[9,19] Of the candidates for the role of local mediator of metabolic vasodilatation, the most thoroughly researched is adenosine.

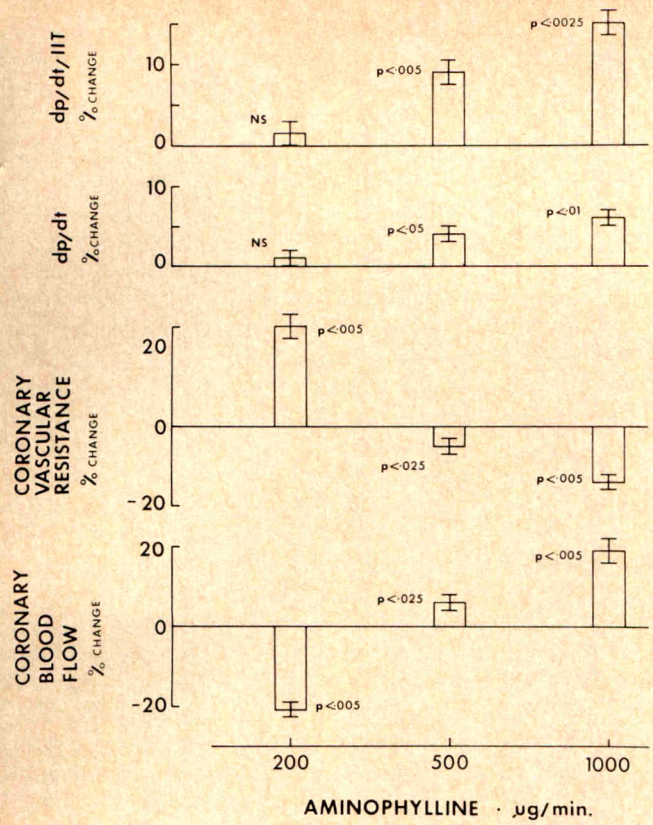

FIGURE 3. The effects of 10-minute close coronary artery infusions of aminophylline on coronary blood flow, coronary vascular resistance and myocardial contractility in a donor dog heart transplanted into the neck of an anesthetized recipient dog (see text). Low-dose infusions reduced coronary flow and increased coronary vascular resistance without changing retractibility, whereas higher doses increased flow contractility. There were no significant changes in donor heart rate or perfusion pressure. Values are mean ± standard error. dp/dt = peak rate of change of donor heart intraventricular pressure; IIT = integrated isometric tension. Reproduced from Paoloni and Wilcken[30] with permission of the publisher.

Adenosine

The development of the adenosine hypothesis has been largely a result of the work of Berne et al, which is summarized in their recent review,[9] from which Figure 2 of the present report is reproduced. Adenosine monophosphate production reflects the degree of adenosine triphosphate utilization and hence the energy state of the cell. The enzyme that dephosphorylates adenosine monophosphate to adenosine, 5′-nucleotidase, appears to be conveniently situated at the cell membrane, in the T tubules, and in the cells surrounding capillaries, the pericytes. Adenosine moves quickly through cell membranes into the interstitial space. There it may dilate arterioles and enhance oxygen delivery, which then reduces the production of adenosine monophosphate and of adenosine. Additional adenosine may reenter the cell or be deaminated in red cells by adenosine deaminase.

Adenosine fulfills many of the conditions required for it to be a metabolic coupling agent linking coronary blood flow to myocardial oxygen demand. It is present in measurable concentrations in the heart and in amounts related to myocardial oxygen requirements; levels change significantly even during a single cardiac cycle.[22] It can be detected, together with its metabolites, in coronary venous blood specimens from humans during myocardial ischemia induced by pacing.[23] In a variety of animal experiments there has generally been good correlation between the degree of coronary vasodilation and the amount of adenosine released.[9,19,24] There is convincing evidence that adenosine acts on a receptor at the smooth muscle cell surface in that high-molecular-weight adenosine derivatives and protein-AMP conjugates that are too large to enter cells and are not inactivated by adenosine deaminase show the same coronary vasodilator activity as adenosine.[25–27]

The principal problem with the adenosine hypothesis has been that drugs that antagonize or potentiate adenosine-induced coronary blood flow responses should modify flow responses to increased myocardial oxygen demand; the experimental data reveal conflicting results. Aminophylline inhibits competitively the coronary vasodilator actions of adenosine.[28,29] Studies from this laboratory showed that low-dose close coronary artery infusions of aminophylline in a transplanted dog heart model, similar to a Langendorff preparation, reduced coronary blood flow at constant perfusing pressure without altering myocardial contractility or heart rate (Fig. 3).[30] Higher doses increased coronary blood flow and myocardial contractility without changing the heart rate. Alpha-adrenoceptor blockade did not affect the low-dose vasoconstrictor response in this isolated heart preparation. A similar biphasic coronary blood flow response to aminophylline has also been shown recently in conscious dogs,[31] but the low-dose vasoconstrictor effect appeared to be alpha-adrenoceptor–mediated. Thus, although we had no direct proof that adenosine blockade was responsible for the low-dose coronary vasoconstrictor response in our preparation, it could have been produced by inhibition of the vasodilator action of locally produced adenosine and therefore consistent with the adenosine hypothesis.

There have been many studies reporting the effects of adenosine potentiating (dipyridamole and lidoflazine) and inhibiting (theophylline and aminophylline) agents on myocardial reactive hyperemia. Although earlier results were conflicting, more recent findings are consistent and have been summarized.[19,24] Drugs which profoundly alter adenosine-induced vasodilatation have little effect on hyperemic responses after occlusions of <10 seconds but may appropriately modify responses after release of occlusions lasting >30 seconds. These results pose problems for the adenosine hypothesis.

A different problem from the adenosine hypothesis stems from the recent work of Downey et al.[32] They showed that regional myocardial hypoxia produced by perfusion with blood of low oxygen partial pressure produced coronary vasodilatation of a degree similar to that induced by ischemic hypoxia, and that although ischemic myocardial hypoxia increased tissue concentrations of adenosine, nonischemic myocardial hypoxia reduced them. These findings run counter to previous observations that showed an increase in adenosine re-

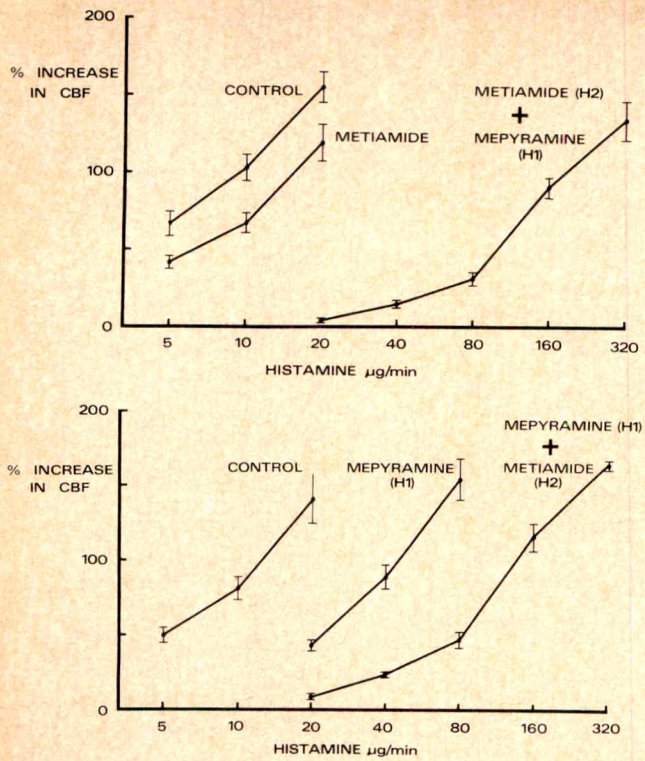

FIGURE 4. Top, dose-response curves determined by close-circumflex coronary artery histamine infusions in anesthetized dogs before and after blockade of the H_2 receptor with metiamide (100 μg/min) and the H_1 receptor with mepyramine (100 μg/min). Heart rate and blood pressure were unchanged (see text). CBF = coronary blood flow. Values are mean ± standard error. Reproduced from Giles et al[39] with permission of the publisher. **Bottom,** as in A except that the H_1 receptor was blocked first with mepyramine (100 μg/min) and then metiamide (100 μg/min) given so that both H_1 and H_2 receptors were blocked. Values are mean ± standard error. Both mepyramine and metiamide antagonize histamine-induced coronary vasodilatation, and the combination of the 2 shift the dose-response curve further to the right than either alone. Vasodilation is attenuated more by mepyramine, suggesting that H_1 receptors predominate. Reproduced from Giles et al[39] with permission of the publisher.

lease with any intervention creating an increased myocardial oxygen requirement, including hypoxia, and a good correlation between this increase and elevation in coronary flow.[9,19,24]

Such studies are critically dependent upon the delay between obtaining tissue and freezing it, but if the findings of Downey et al[32] are confirmed, they would constitute powerful evidence for the importance of oxygen or vasodilator metabolites other than adenosine or both contributing to coronary vasodilatation associated with nonischemic hypoxia.

Other Possible Vasodilator Mediators

It is beyond the scope of this review to consider other vasodilator mediators in detail. The effects of prostaglandins and the local release of neurotransmitters in neurally mediated changes are considered elsewhere in this symposium. Parratt[19] reviewed the evidence for contributions from carbon dioxide and locally released potassium; the results of recent work make it likely that these act as vasodilator mediators under certain circumstances without fully accounting for responses. Potassium release, for example, occurs after a 15-second coronary artery occlusion, but the time course of the release and the return toward normal is not the same as that of the hyperemic response.[33] Forrester[34] has discussed the evidence for a role for adenosine triphosphate.[34] It is a more powerful vasodilator than adenosine, and this action is unaffected by aminophylline.[35] There is, however, a fundamental problem of membrane permeability with adenosine triphosphate, in that leakage from myocardial cells probably only occurs with membrane damage. Under these conditions, it must have important local vasodilator effects.

Histamine is of special interest because it is present in high concentration in the human heart and is a powerful vasoactive agent. It may have a regulatory role in adrenergic neurotransmission,[36] but as yet no role for it in coronary flow regulation has been defined. Its cardiovascular actions have been extensively reviewed recently.[37] Histamine is a powerful dilator of small resistance vessels in the dog heart and human peripheral circulation, but constricts isolated large conducting coronary arteries in humans.[38] The involvement of H_1 and H_2 receptors in the dilatation of coronary resistance vessels in the dog is shown in experiments summarized in Figure 4, in which close-circumflex coronary artery infusions of histamine were given before and after H_1,H_2 and combined H_1- and H_2-receptor blockade. The dose-related increases in coronary blood flow that occurred without change in heart rate or blood pressure were attenuated more by H_1- than H_2-receptor blockade, but the effect of each potentiated the effect of the other. We could find no evidence in these studies for an involvement of histamine in postocclusion hyperemia in that this response was unaffected by combined H_1- and H_2-receptor blockade, which markedly attenuated histamine-induced flow increases of the same magnitude as those produced during reactive hyperemia.[39] But the same could be said for adenosine in similar experiments with aminophylline blockade.[35]

Myogenic Factors in Local Flow Regulation

The myogenic hypothesis and the idea of autoregulation of blood flow—that is, the maintenance of a relatively constant blood flow, over a wide range of perfusing pressures, to tissues whose myocardial oxygen demand remains unchanged—stems from the work of Bayliss.[40] The myogenic hypothesis suggests that elevation of vascular transmural pressure stretches arteriolar smooth muscle cells, inducing lengthened myofibrils to contract more forcefully, and that the ensuing vasoconstriction keeps contained a potential increase in blood flow. Lowering vascular transmural pressure does the reverse by reducing the forces tending to elongate circularly arranged vascular smooth muscle.

The myogenic response has been reviewed recently relative to the circulation as a whole[41] and the coronary circulation specifically.[42] These reviews summarize the powerful evidence for the existence of myogenic effects in the renal, limb, splanchnic and cerebral circulation, although direct proof is lacking in the latter. In the

coronary circulation, however, the evidence in inferential and studies have been hampered by the difficulty of separating metabolic from possible myogenic effects during autoregulation and myocardial reactive hyperemia. The latter has been extensively studied because it is a highly reproducible response in which metabolic and transmural pressure changes occur, and the magnitude of the response is not explicable in terms of metabolic mechanisms alone.[43] Studies from this laboratory in which 1 or 2 cardiac cycle coronary artery occlusions were performed in conscious and anesthetized dogs resulted in marked reactive hyperemia responses even though these would not, according to current knowledge, lower intracellular myocardial oxygen partial pressure.[44] Similar responses to single cycle occlusions have lately been shown to occur also in man.[45] Nevertheless the finding of significant variations in myocardial adenosine throughout individual cardiac cycles makes it theoretically possible for adenosine to be the mediator.[22] However, these responses to short occlusions cannot be attenuated by aminophylline nor can this discrepancy be explained by enhanced adenosine-induced vasodilator activity in the presence of reduced oxygen partial pressure and increased hydrogen ion concentrations, as suggested by Merrill et al[46]; subsequent experiments by the same group exclude that possibility.[47]

Two recent findings may further clarify the mechanisms of myocardial reactive hyperemia. Hintze and Vatner[48] showed in conscious dogs that large coronary arteries respond to release of 20-second coronary artery occlusions with delayed dilatation. In their experiments, this reached a maximum of 62 ± 4 seconds after release, when arterial cross-sectional area was 32 ± 9% above the control level; at this time, coronary flow had returned to preocclusion values.

These data are interesting in view of the reduced coronary vascular activity that occurs after a reactive hyperemic response and lasts for several minutes.[49,50] Taken together, these findings may provide an explanation for the dependency of myocardial reactive hyperemia on coronary artery pressure found by Dole et al,[51] consistent with a transient depression of the normal vascular reactivity to postocclusion pressure. As Dole et al suggest, a passive component to reactive hyperemia could account for the consistent postrelease overpayment of the flow debt in the heart.

The most recent finding is that the slow-channel calcium blockers nifedipine and verapamil markedly attenuate reactive hyperemic responses after release of short coronary artery occlusions (up to 30 seconds), when given in amounts that do not alter myocardial oxygen consumption, and that this is associated with a variable blockade of vasodilator responses to infused adenosine.[52] Diltiazem also reduces postocclusion hyperemia (10-second occlusions) but appears less effective.[53] These recent observations all suggest that alterations in intrinsic vascular smooth muscle function during and after the reactive hyperemic response do occur and cannot be explained entirely in terms either of metabolic or myogenic mechanisms as they are understood.

Belloni[24] emphasized the distinctions that should be drawn between the functional hyperemia resulting from increased myocardial activity, postocclusion hyperemia after release of a coronary artery occlusion, hyperemia associated with systemic hypoxia, and the hyperemia accompanying a decrease in perfusion pressure over the autoregulatory range. It is unlikely that these widely differing responses can be explained in terms of a single vasodilator mechanism; the involvement of several mechanisms, or combinations of mechanisms, is much more likely.

Coronary Anatomy and Blood Flow

Changes in vascular smooth muscle function alter flow within limits dictated by coronary anatomy. The latter must influence the distribution of flow. The anatomy of the coronary circulation and the extent of its collateral supply varies greatly between species; for example, there is a profuse collateral circulation in the dog not present in the pig, whose coronary anatomy closely resembles that of humans.[54] In humans, the size of named coronary arteries and the disposition of dominance between right and left coronary vascular systems vary greatly from person to person. The differences are presumably genetically determined. Two of my patients, 40-year-old monozygotic twins investigated for coronary artery disease, are of considerable interest in this regard in that each had identical coronary anatomy in terms of size of major arteries and the extent of the myocardium each supplied (Wilcken DEL, unpublished data).

Occlusions of a major coronary artery produce left ventricular impairment widely differing in extent and severity in different patients. This is evident from studies of patients with total left anterior descending artery obstruction as their only coronary artery lesion.[55] Whether the obstruction is proximal or distal is obviously important; for example, Brooks et al[55] found, not surprisingly, that patients with proximal obstructions were more likely to have a greater reduction in left ventricular function than those whose obstructions were distal to the first septal perforator branch. The major determinant of the variability is the amount of myocardium supplied by the obstructed artery, collaterals notwithstanding.[56] Because the area supplied by any individual artery varies from patient to patient, local, genetically determined, anatomic factors must be important in the pathophysiologic features of the coronary circulation. This fact, perhaps self-evident, is poorly appreciated.

General Conclusions

The concept of a transmural series of vascular waterfalls due to a gradient of compressing diastolic tissue pressures from the epicardium to the endocardium awaits confirmation. It has broad implications in relation to subendocardial ischemia and to the effect of hypertrophy on regional blood flow. Although present data show a significant role for adenosine in coronary blood flow regulation to be likely, it is also unlikely that adenosine is the sole mediator. Indeed, considering the importance of metabolic vasodilatation for norma

cardiac function, a unitary theory of regulation with a single vasodilator mediator would seem to lack built-in safety factors. As Parratt[19] has pointed out, it is unlikely that there is any 1 sole mediator of every kind of physiologic coronary vasodilatation. Evidence is accumulating for interrelations between naturally occurring coronary vasodilators in mediating flow responses, with important links provided by prostaglandins. The recent demonstration of reduced coronary blood flow in man after prostaglandin synthetase blockade with indomethacin is important evidence favoring a role for prostaglandins in human coronary flow regulation.[57] There is also evidence for the importance of intrinsic changes in vascular smooth muscle in postocclusion hyperemia and for the significance of anatomic variability in the coronary arteries in relation to myocardial damage in pathophysiologic states.

Alpha-Adrenergic Regulation of the Coronary Circulation in the Conscious Dog

STEPHEN F. VATNER, MD

To examine the role of neural and humoral factors in the control of coronary vasoactivity in conscious animals in which the complicating effects of general anesthesia and recent surgery were absent, dogs were instrumented with miniature pressure gauges in the aorta and left ventricle to measure aortic and left ventricular pressures and with flow probes in the left circumflex coronary artery to measure coronary blood flow. Several weeks after recovery from operation, experiments were conducted in the conscious dogs. Stimulation of the carotid chemoreceptor reflex elicted a biphasic response; initially striking reflex coronary vasodilation was observed: Coronary blood flow tripled even after changes in metabolic factors were minimized by pretreatment with propranolol. The chemoreceptor reflex coronary vasodilation was mediated both by cholinergic activation and withdrawal of alpha-adrenergic tone. The second phase of the response involved an increase in coronary vascular resistance, associated with elevated arterial pressure and an absolute reduction in coronary blood flow and coronary sinus oxygen content. The later period of coronary vasoconstriction was abolished by alpha-adrenergic blockade. Intravenous infusion of the alpha-adrenergic agonist methoxamine increased mean arterial pressure by 65 ± 5% and total coronary vascular resistance by 92 ± 14%. To determine whether the large coronary arteries were also under autonomic control, the dogs were instrumented with a pair of ultrasonic crystals on opposing surfaces of the left circumflex coronary artery to measure its diameter directly and continuously. Methoxamine reduced coronary cross-sectional area substantially, thereby constricting large coronary arteries and resistance coronary vessels. Thus, while the coronary arteries are regulated by changes in myocardial metabolic demands, they are also responsive to changes in neural stimuli. The most striking changes were observed with augmentation and withdrawal of alpha-adrenergic constrictor tone, which appear to be important in the control of large as well as small coronary vessels.

Until recently, neural control of the coronary circulation was considered a trivial component in the multifactorial control of coronary blood flow and vascular resistance. The current interest in coronary vasospasm, increased interest in the autonomic control of the coronary circulation and studies in experimental animals and in humans have corroborated its importance.

This review will not present all evidence for autonomic coronary vascular regulation, but will highlight the studies demonstrating the best examples of autonomic modulation of large and small coronary vessels. The studies described have been conducted in chronically instrumented, conscious animals. The advantages of this technique include the ability to measure variables in the coronary circulation and left ventricular function instantaneously and continuously and the absence of the complicating influences of anesthesia and recent surgery.[1]

Methods

Mongrel dogs were anesthetized with pentobarbital sodium 30 mg/kg. All transducers were implanted through a thoracotomy in the fifth left intercostal space. To measure coronary blood flow, an electromagnetic or Doppler flow transducer was implanted in the left circumflex coronary artery. In dogs in which an electromagnetic flowmeter was used, a hydraulic occluder was implanted distally to confirm zero blood flow. Pacing electrodes were implanted on the right atrium. To measure left ventricular (LV) pressure and the first derivative of LV pressure (LV dP/dt), miniature pressure gauges (Konigsberg Instruments) were implanted in the left ventricle. Miniature pressure gauges were also implanted in the descending thoracic aorta. Heparin-filled Tygon™ (Norton)

catheters were implanted in the left atrium and descending thoracic aorta. To measure coronary diameter, 2 miniature 7-MHz ultrasonic transducers were implanted on opposing surfaces of the left circumflex coronary artery 3 to 6 cm from its origin. The ultrasonic transducers were covered with Insl-X® (Insl-X Products) and attached to a Dacron® (Dupont) backing. The Dacron was sutured to the outer adventitia of the coronary artery using Ethicon 5-0 suture. To measure right coronary artery blood flow and right ventricular pressure, a Doppler flow transducer was implanted in the right coronary artery and a miniature pressure gauge was implanted in the right ventricle through a right thoracotomy. During a subsequent operation using pentobarbital sodium, 30 mg/kg, and a right thoracotomy approach, a Tygon catheter was implanted in the coronary sinus in 5 dogs. In dogs in which carotid chemoreceptor reflex stimulation (CCRS) was to be carried out, a Tygon catheter was implanted in the common carotid artery just proximal to the carotid body using anesthesia with 10 mg/kg of sodium thiamylal.

LV and aortic pressures were measured with the implanted miniature gauges, which were calculated in vitro with a mercury manometer and cross-calibrated in vivo with pressure measurements from the aortic and left atrial catheters. Coronary blood flow was measured using a Benton square-wave electromagnetic flowmeter or a Doppler ultrasonic flowmeter.[2] Phasic coronary arterial diameter was measured instantaneously and continuously with an improved ultrasonic dimension gauge.[3–5] The frequency response of the dimension gauge is flat to 100 Hz. The drift of the instrument is minimal (<0.01 mm in 6 hours). To further ensure data reliability, repeated calibration references were obtained regularly throughout the experiments and the received ultrasonic signal was monitored continuously on an oscilloscope. Major changes in alignment of the crystals were detected in the received signal and invalidated the experiment.

The experiments were conducted 1 to 3 weeks after operation in healthy, conscious dogs. Left circumflex coronary arterial diameter, arterial pressure, LV pressure, LV dP/dt, left atrial pressure, left circumflex coronary artery blood flow and heart rate were continuously measured during a control period and during interventions. The interventions were performed on different experimental days.

The data were recorded on a 14-channel magnetic tape recorder (Bell & Howell) and played back on 2 multichannel oscillographs (Gould-Brush). Mean pressures and coronary diameters and blood flows were measured using RC filters with 2-second time constants. LV dP/dt was derived by differentiating the LV pressure signal using a Philbrick operational amplifier (Teledyne Philbrick) connected as a differentiator and with a frequency response of 700 Hz. A triangular signal with a known slope (rate of change) was substituted for the pressure signal to calibrate the differentiator directly. Heart rate was measured continuously with a cardiotachometer triggered by the LV pressure pulse. While the external coronary diameter was measured continuously, the internal radius was calculated by determining at autopsy the thickness and mass of a coronary artery with known length from the point at which the piezoelectric crystals were located. Thus, wall volume could be calculated as the quotient of mass and density ($d = 1.06\ g/cm^3$). After the wall volume, the wall thickness value and external diameter were determined, and the internal coronary diameter and cross-sectional area, which reflect large coronary arterial responses, were calculated. Late diastolic coronary resistance, which reflects primarily small coronary vessel resistance, was calculated as the quotient of late diastolic arterial pressure and late diastolic coronary blood flow. The mean and standard deviation were calculated for all variables.

FIGURE 1. The instrumentation for measurement and transmission o aortic and left ventricular pressures and coronary blood flow during exercise was carried by each dog in a backpack. The signals were transmitted to a mobile recording until that consisted of a van carrying FM communication receivers, subcarrier discriminators, signal processing electronics and a multichannel tape recorder. Protocols

Experimental protocols: *Response to carotid chemoreceptor reflex stimulation: spontaneous respiration:* Heart rate was held constant (ventricular pacing) by electrical stimulation from an external pacemaker in all experiments. After control measurements of all variables, CCRS was achieved by a bolus (1 ml total volume) injection of nicotine into the catheter chronically implanted in 1 of the main carotid arteries. Increasing doses of nicotine (range from 1 to 10 μg) were administered to determine the dose of nicotine required to achieve peak coronary vascular effects in each dog. This dose was used throughout the remainder of the study. Triplicate responses of the measured variables to CCRS (which in the conscious, spontaneously respiring dog also elicits the pulmonary inflation reflex) were then determined. The cardiovascular effects elicited by the intracarotid injection of nicotine in this dose range are entirely reflex in nature in that the nicotine-induced effects are abolished by ipsilateral carotid sinus nerve section.[6–10] The integrated coronary vascular response to combined carotid chemoreceptor and pulmonary inflation reflex activation was further assessed after the sequential intravenous administration of the beta-adrenergic antagonist propranolol hydrochloride (1.0 mg/kg), the cholinergic antagonists atropine sulfate or atropine methyl bromide (0.1 mg/kg) and the alpha-adrenergic antagonist phentolamine (2.0 mg/kg). The adequacy of beta-adrenergic blockade was tested with isoproterenol (1.0 μg/kg, intravenously), that of cholinergic blockade with acetylcholine (40 μg/kg, intravenously), and that of alpha-adrenergic blockade with norepinephrine (1.0 μg/kg, intravenously).

Response to carotid chemoreceptor stimulation: controlled respiration: To avoid the confounding influences of changes in intrathoracic pressure and arterial blood gases associated with pulmonary inflation reflex activation, the effects of intracarotid nicotine were assessed on a separate day when ventilation was controlled by a respirator during succinylcholine chloride infusion (0.1 mg/kg/min, intravenously).

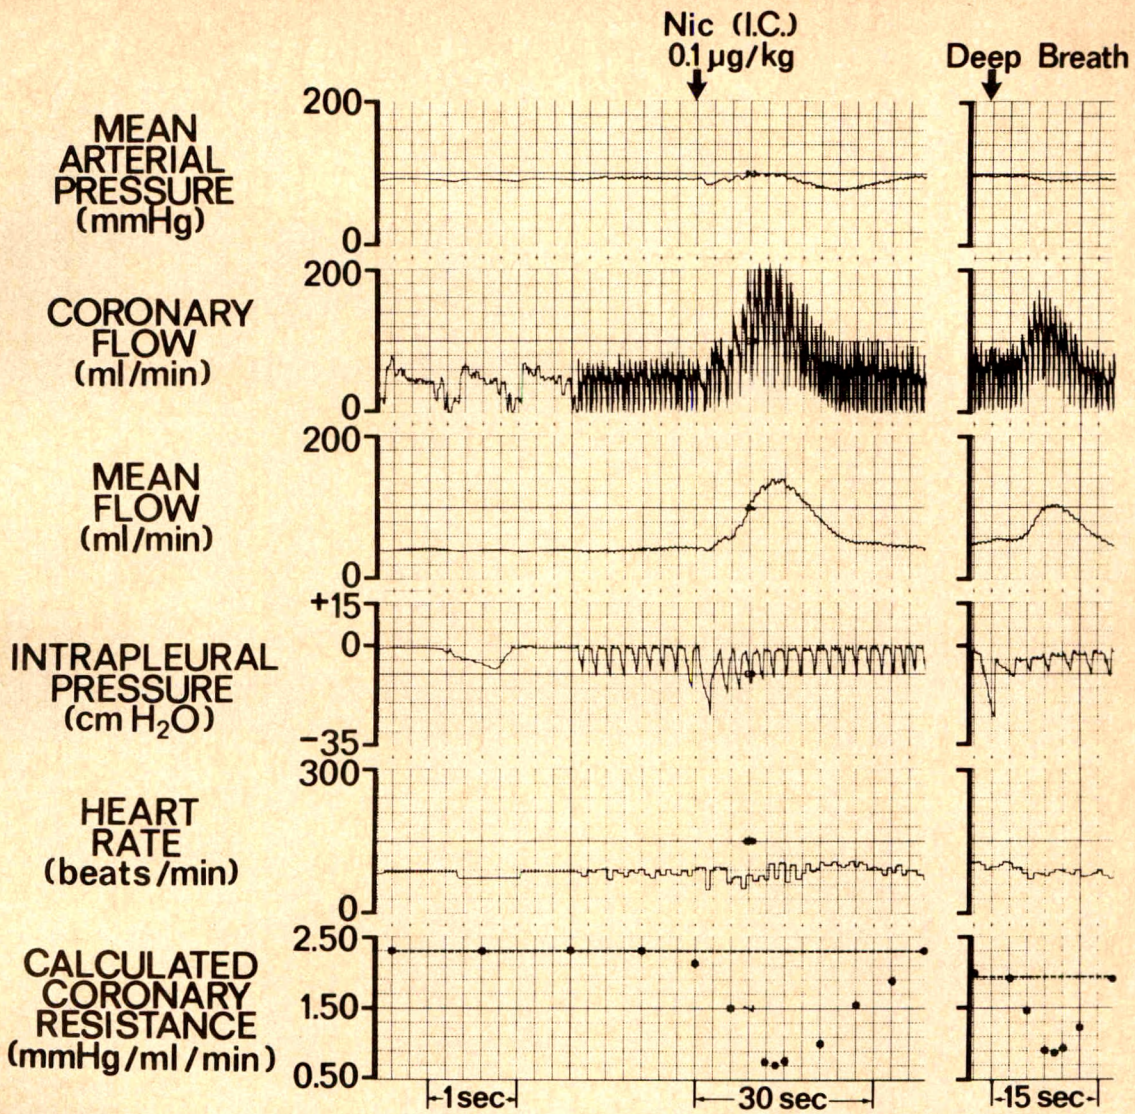

FIGURE 2. Effects of intracarotid (I.C.) administration of nicotine (NIC) in a conscious dog with spontaneous rhythm (**left section**) on mean arterial blood pressure, phasic and mean coronary blood flows, intrapleural pressure, heart rate and calculated coronary resistance. Intracarotid administration of nicotine elicited a striking increase in coronary flow and a reduction in coronary resistance immediately after an increase in the depth of respiration (indicated by the change in intrapleural pressure). The effects of a spontaneous deep breath in the same conscious dog are shown in the **second section.** The effects of the same dose (**third section**) and a much larger dose of intracarotid nicotine (**fourth section**) in the same dog are also shown after general anesthesia was induced with sodium pentobarbital. A spontaneous deep breath elicited a period of coronary dilation similar to that which occurred with intracarotid nicotine in the conscious state, but nicotine administered in the anesthetized dog did not evoke a substantial change in either respiration or coronary vasodilation. Reproduced from Circ Res 1975;37:664–673 with permission of the publisher.

Before these experiments, this protocol was reviewed by the Animal Care Committee of the institution and was found to conform to the guidelines for research in experimental animals. All dogs were lightly anesthetized with a short-acting barbiturate (thiamylal sodium, 2.0 mg/kg, intravenously) before intubation and succinylcholine administration. The larynx was sprayed with a topical anesthetic (Cetacaine®, Cetylite Industries) and the endotracheal tube was coated with a lidocaine paste. Because these dogs were only lightly tranquilized, no intervention was performed that would not be fully tolerated by the conscious dog in the absence of succinylcholine. At the end of each experiment, the dogs were given an intramuscular injection of morphine sulfate (10 mg) as an analgesic.

The right and left coronary response to selective CCRS, as well as changes in arterial and coronary sinus blood gases and oxygen contents, were first assessed with the autonomic nervous system intact and then after the sequential intravenous administration (doses noted above) of propranolol, atropine and phentolamine.

Responses to free ranging exercise: During the exercise periods, instrumentation necessary for the continuous transmission of aortic pressure, LV pressure and left circumflex coronary blood flow signals by radiotelemetry (described later) was carried by each dog in a backpack. The exercise regimen consisted of each dog running freely behind a mobile recording van over a hilly half-mile course (Fig. 1) in the absence of pharmacologic blocking agent (unblocked condition), or 3 to 5 minutes after the intravenous administration of a beta-receptor blocker (propranolol hydrochloride 1 mg/kg), an alpha-receptor blocker (phentolamine, 1 to 2 mg/kg) or after combined beta and alpha blockades. Heart rate was held constant during exercise by electrical pacing. The entire exercise protocol for each dog usually was com-

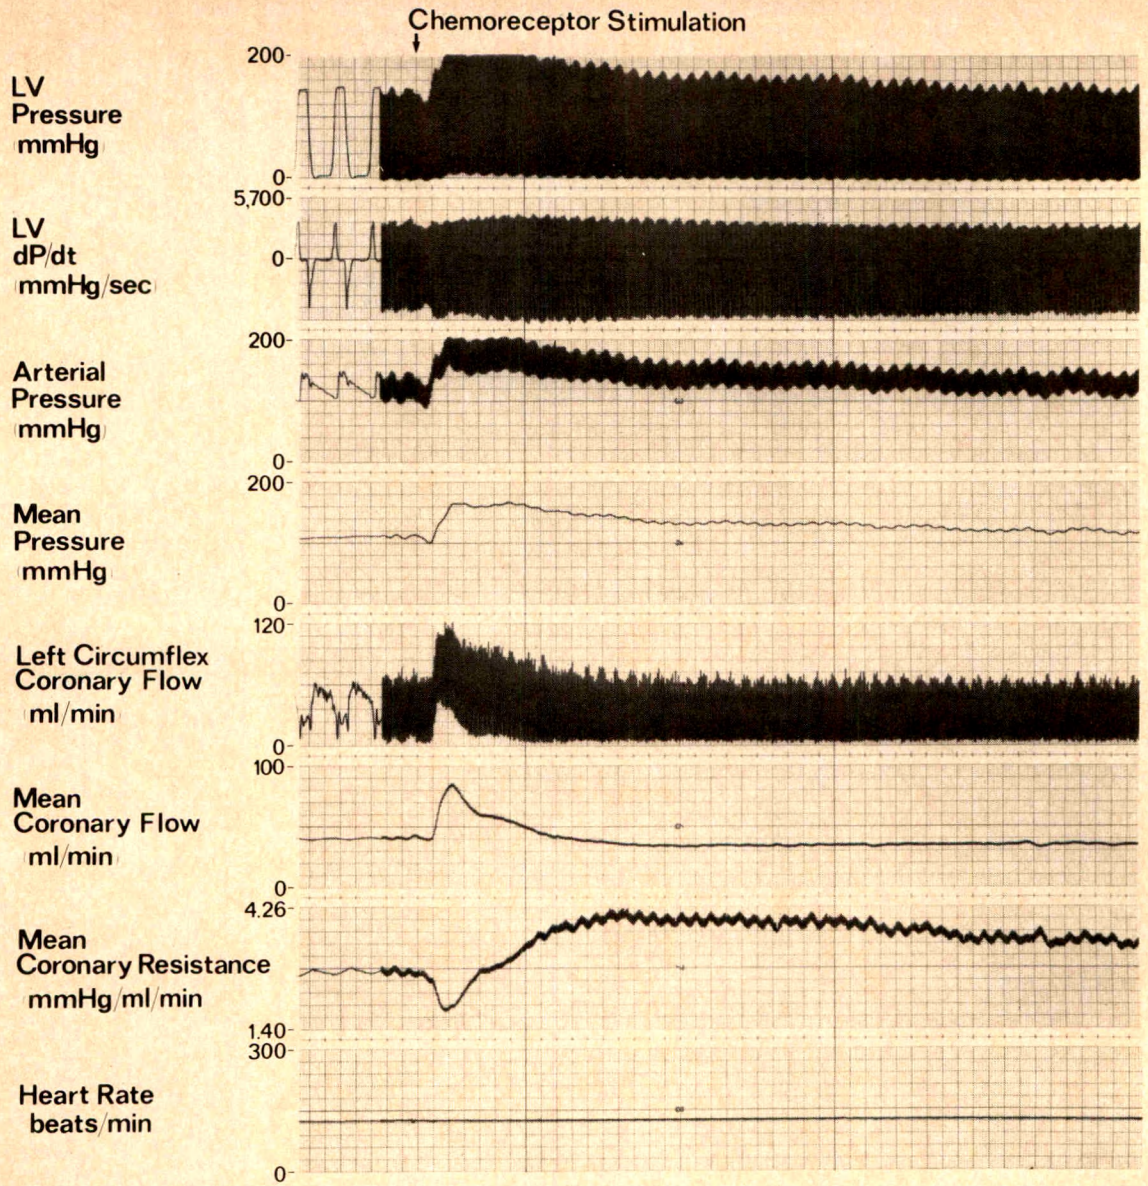

FIGURE 3. Effects of intracarotid administration of nicotine in a conscious dog with controlled ventilation of left ventricular (LV) pressure, LV dP/dt phasic and mean arterial pressure and left circumflex coronary blood flow, calculated mean coronary resistance and heart rate. Chemorecepto stimulation elicited an initial striking increase in coronary flow and a reduction in coronary vascular resistance. This was followed by a period o coronary vasocontriction characterized by a reduction in coronary blood flow in the face of a sustained increase in arterial pressure. This perio of vasoconstriction was also characterized by a decrease in coronary sinus oxygen content and could be eliminated by prior alpha-adrenergic recepto blockade.

pleted over a 1-week period, with a maximum of 2 exercise periods per day. Three- to 5-hour rest intervals were allowed between exercise periods on a given day. The order of the exercise regimen was randomized to avoid the potentially confounding influences of dog training or altered sensitivity to the adrenergic antagonists that may accompany multiple exercise periods. Moreover, duplicate exercise runs were performed in selected dogs to assess the consistency of the responses of the measured variables during exercise.

System for telemetry of data: Continuous measurements of left circumflex coronary blood flow, heart rate, aortic pressure and LV pressure were radiotelemetered while the dogs were standing quietly at rest or running freely in the field behind a mobile recording van (Fig. 1). Speeds of 25 to 35 mph were achieved routinely by these dogs in the absence of any blocking agent. Whereas running speeds were generally slowe in the presence of the adrenergic antagonists (10 to 20 mph) in all cases the severity of the exercise period (as reflected by the time required to traverse the exercise course) afte blockade of alpha-receptor activity was either less than o equal to the level of exercise with alpha-receptor activity in tact. Descriptions of the instrumentation and techniques use to transmit continuously the left circumflex coronary bloo flow, aortic pressure and LV pressure signals by radiotelem etry have been reported in detail.[3,11] Briefly, the signals fron the aortic and LV pressure implant system were transmitte from the dogs to the remote recording unit by way of a FM/FM subcarrier telemetry system. The Doppler ultrasoni flowmeter signal was frequency modulated on the carrie frequency and did not require an additional subcarrier. Th

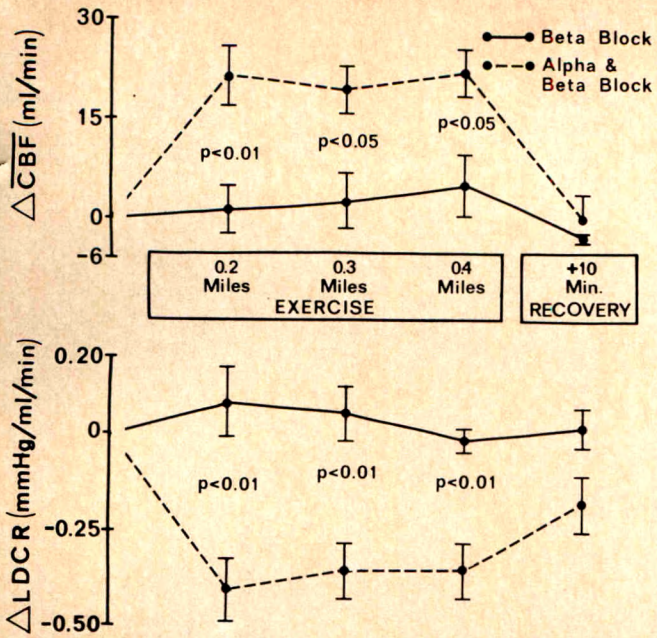

FIGURE 4. Average (± standard error of the mean [SEM]) changes in mean left circumflex coronary blood flow (ΔCBF) and late diastolic coronary resistance (ΔLDCR) of 9 dogs during spontaneous exercise at 0.2, 0.3 and 0.4 miles and 10 minutes after cessation of exercise after pretreatment with propranolol with alpha-receptor activity intact (beta block) and after blockade of alpha-receptor activity (alpha and beta block). Heart rate was held constant at approximately 190 beats/min by electrical pacing. Reproduced from Circ Res 1979; 45: 654–600 with permission of the publisher.

mobile recording unit consisted of a van carrying FM communication receivers, subcarrier discriminators, signal processing electronics, and a multichannel tape recorder (Honeywell model 5600-C). A commercial whip antenna mounted on the roof of the van received the signals transmitted from the dog. Power for the equipment was obtained from two direct-current (DC) to alternating-current (AC) inverters (Heathkit model MP-14 and Wilmore model 1057-12). Each of these units was powered by one 12-V battery. The FM tuners (Heathkit model AJ-15) were modified to disable the FM deemphasis network and multiplex circuitry, providing video response sufficient to recover the modulated subcarrier signals. The output of the FM tuners was applied directly to the input of the 2 subcarrier frequency discriminators (Airpax model FDS-30). These discriminators converted the frequency modulation signals to DC voltages proportional to the signals measured in the dog. These DC voltages then were applied to FM channels of the instrumentation tape recorder. During the experiment, commentary was recorded on a voice channel of the tape recorder.

Results and Discussion

Alpha-adrenergically mediated coronary vasodilation: Activation of the carotid chemoreceptor and pulmonary inflation reflexes provides the most striking example of alpha-adrenergically mediated coronary vasodilation. In the conscious dogs breathing spontaneously, injections of minute quantities of either nicotine or cyanide into the common carotid artery just proximal to the carotid body elicits a marked increase in ventilation, which is rapidly followed by striking (2- to 3-fold) increases in coronary blood flow. This increase in coronary blood flow occurs in the face of little change in arterial pressure (Fig. 2), no change in heart rate or with heart rate held constant, and before any significant alterations in LV wall tension and myocardial contractility. Furthermore, the increase in coronary blood flow is accompanied by an increase in coronary sinus oxygen content and reduction in the arteriovenous oxygen difference. Thus, the dilation is clearly not mediated by metabolic mechanisms.

To confirm that the afferent pathway was neural, experiments were conducted after section of the ipsilateral carotid sinus nerve. Under these conditions, absolutely no effect was observed after intracarotid injection of either nicotine or cyanide. To confirm that the efferent pathway was neurally mediated, the experiments were conducted in the presence and absence of selective and combined autonomic blockade. Since the peak coronary vasodilation after CCRS preceded inotropic changes, it could be predicted that beta-adrenergic blockade would not modify the coronary vasodilation due to CCRS. Indeed, that is what was observed. Atropine, 0.1 mg/kg, increased cardiac rate, and consequently partially dilated the coronary bed on a metabolic basis. However, CCRS in the presence of cholinergic blockade still induced significant vasodilation, attaining peak levels similar to those in the absence of cholinergic blockade. The addition of phentolamine almost abolished the coronary vasodilation in response to CCRS.

Thus, CCRS in the conscious dog elicits striking coronary vasodilation. The efferent mechanism of this vasodilation appears to involve withdrawal of alpha-adrenergic tone, since it is blocked by phentolamine.

It is important to keep in mind that these experiments were carried out in conscious dogs respiring spontaneously. The CCRS-induced coronary vasodilation was always preceded by an increase in depth of respiration. The afferent mechanism responsible for the vasodilation may well be the pulmonary inflation reflex and not the carotid chemoreceptor reflex. A similar coronary vasodilator response can be evoked by increasing the depth of ventilation either spontaneously (deep breath) or mechanically (increasing the volume of a respirator).[6] These responses are eliminated by alpha-adrenergic receptor blockade or attenuated markedly by vagotomy.[6] In contrast, carotid chemoreceptor reflex–induced coronary vasodilation can be blocked by atropine.[6,12]

Alpha-adrenergic receptor coronary vasoconstriction: Most evidence for alpha-adrenergically mediated vasoconstriction is derived from experiments in which coronary driving pressure increases and coronary blood flow remains constant, thereby eliciting an increase in calculated coronary vascular resistance.[13–18] These increases in calculated coronary vascular resistance can be eliminated by alpha-adrenergic receptor blockade.[13–18]

Recently, we observed an example of coronary vasoconstriction that is characterized by an increase in coronary driving pressure and absolute reduction in coronary blood flow.[10] This response occurs with CCRS,

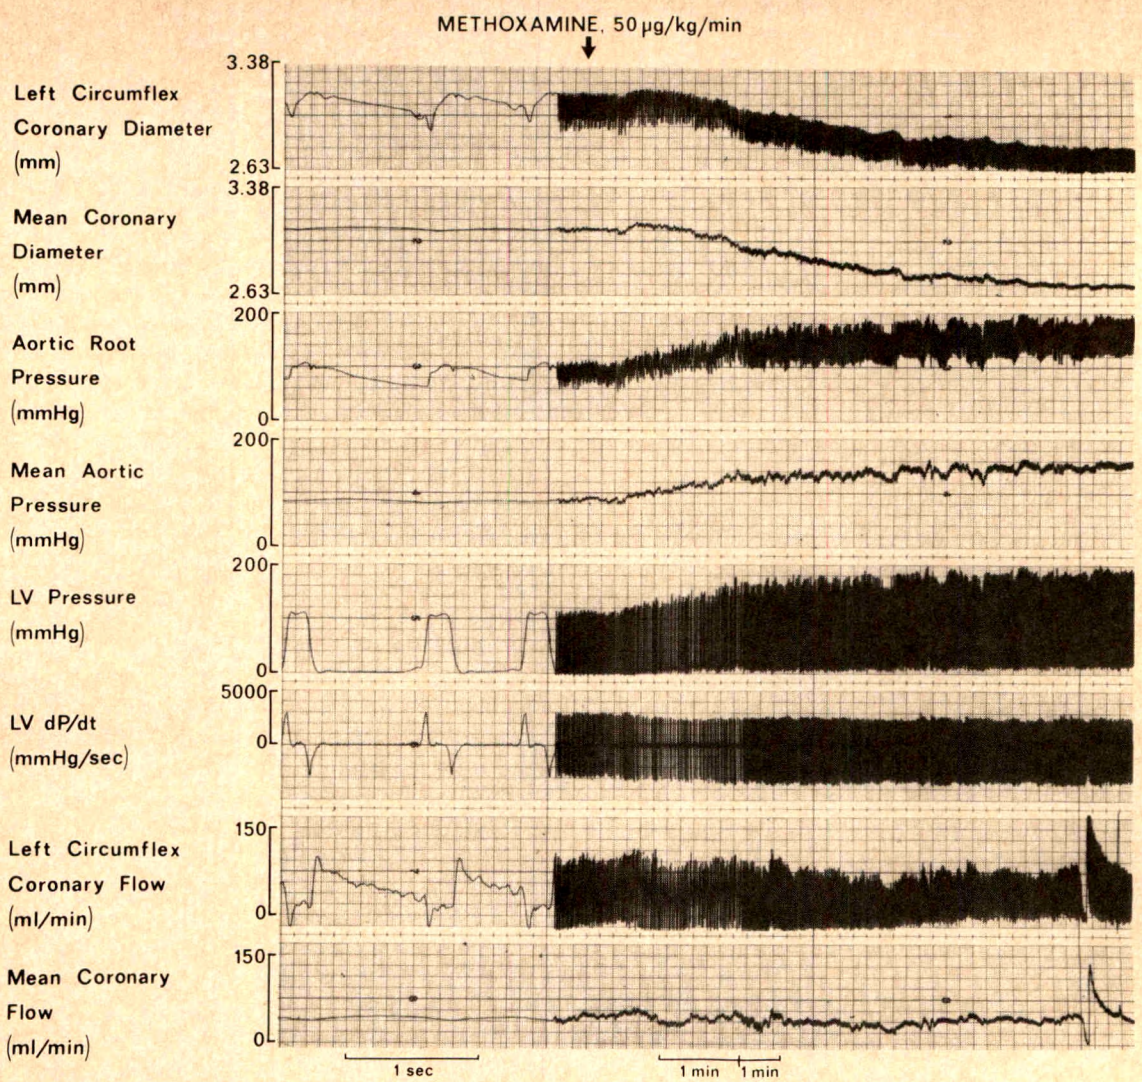

FIGURE 5. The effects of a 10-minute infusion of methoxamine, 50 μg/kg/min, in a conscious dog are depicted on simultaneous and continuous measurements of phasic and mean left circumflex coronary artery diameter, aortic root pressure, left ventricular (LV) pressure, LV dP/dt and phasic and mean left circumflex coronary blood flow. Methoxamine increased coronary diameters only initially and transiently and then induced striking sustained reductions in coronary diameters at a markedly increased aortic pressure. A mechanical zero for the blood flow recording is shown at the end of the experiment. The marked sinus arrhythmia is characteristic of the conscious dog. Reproduced from J Clin Invest 1980;65:5–14 with permission of the publisher.

but later, after the initial period of coronary vasodilation has subsided (Fig. 3). The late period of vasoconstriction is much more prominently displayed in the right coronary circulation than the left. This is probably because CCRS is accompanied by a moderate increase in afterload for the left, but not the right, ventricle. The right coronary artery supplies only the right ventricle in the dog and, thus, would not demonstrate an increase in blood flow due to enhanced myocardial metabolic demands faced by the left ventricle. The period of coronary vasoconstriction is associated with a decrease in coronary sinus oxygen content and a widening of arteriovenous oxygen difference across the heart. This later period of coronary vasoconstriction is not blocked by either beta-adrenergic or cholinergic blockade, but can be virtually eliminated by alpha-adrenergic blockade.

The afferent mechanism of this late period of coronary vasoconstriction is most likely the carotid chemoreceptor reflex, since the response is even more intense in the presence of controlled ventilation,[10] that is, where the complicating influences of the pulmonary inflation reflexes are absent. Moreover, under these conditions atropine eliminates the early vasodilation but leaves intact the later period of vasoconstriction. Therefore, the later vasoconstrictor response is not necessarily linked to the early vasodilator response.

These experiments demonstrate that stimulation of reflex adrenergic neural pathways is powerful enough to reduce coronary blood flow and coronary sinus oxygen content despite an elevation of coronary driving pressure in the conscious animal.

Alpha-adrenergic coronary vasoconstriction during exercise: Severe exercise is associated with intense sympathetic drive to the heart. This intense sympathetic drive may also affect the coronary vessels during severe exercise. To test this hypothesis, we ex-

amined responses to near-maximal exercise in dogs in the presence and absence of alpha-adrenergic receptor blockade. In the presence of alpha-adrenergic receptor blockade, coronary vascular resistance decreased to a significantly lower level than in the absence of alpha-adrenergic receptor blockade.[11] These experiments could be criticized on the basis that heart rate and myocardial contractility were uncontrolled. To obviate these criticisms, exercise was studied with heart rate held constant and after pretreatment with beta-adrenergic receptor blockade, but in the presence and absence of alpha-adrenergic blockade. Again, exercise of similar intensity elicited significantly greater coronary vasodilation in the presence compared with the absence of alpha-adrenergic receptor blockade[11] (Fig. 4). Subsequent studies by Gwirtz and Stone[19] and Heyndrickx et al[20] also demonstrated a component of alpha-adrenergic coronary vasoconstriction during exercise, which was associated with a widening of arteriovenous oxygen difference across the heart. All of these studies suggest that alpha-adrenergically mediated vasoconstriction attenuates the metabolic vasodilation associated with exercise.

Alpha-adrenergic vasoconstriction of large coronary arteries: Until recently, all evidence for large coronary arterial vasoconstriction was indirect. We developed techniques to measure large coronary arterial diameter in conscious animals.[5] To determine whether the large coronary arteries constricted in response to alpha-adrenergic stimulation, we examined responses of these large coronary arteries to an infusion of a potent alpha-adrenergic receptor agonist, methoxamine, 50 μg/kg/min.

Methoxamine elicited a marked increase in peripheral vasoconstriction accompanied by a substantial increase in arterial pressure. It was expected that coronary dimensions would increase passively in response to the elevated distending pressure induced by methoxamine infusion, and this is what was observed initially, but only transiently with methoxamine. However, with continued alpha-adrenergic receptor stimulation, coronary cross-sectional area rapidly returned to control levels and then decreased significantly below control for the remainder of the infusion period (Fig. 5). These data indicate that alpha-adrenergic receptor vasoconstriction of the large coronary arteries is powerful enough to oppose the tendency of arterial pressure to dilate these arteries. Moreover, the changes in vessel caliber cannot be ascribed to a reduction in metabolic requirements of the heart,[21] because heart rate was not significantly different from control, yet preload and afterload were both increased. Calculated total coronary vascular resistance increased 92% with methoxamine, suggesting that vasoconstriction occurred throughout the coronary bed; this is consistent with the results from a recent study in anesthetized dogs by Kelley and Feigl.[18]

These results indicate that in the conscious animal, large coronary vessels not only respond passively to changes in distending pressure, but also undergo substantial active changes in cross-sectional area. Alpha-adrenergic receptor activation reduces coronary cross-sectional area even in the face of marked increases in distending pressure.

Thus, the large and small coronary vessels of conscious dogs are regulated extensively by alpha-adrenergic mechanisms. Whether these mechanisms are of greater importance in the presence of coronary artery disease, and whether they could play a role in the pathogenesis of coronary vasospasm, remains to be determined.

Prostanoids in Platelet-Vascular Interactions

T. JOHN MARTIN, MD, DSc, IAN L. SMITH, BSc, ROGER D. NOLAN, BSc, and GREGORY J. DUSTING, PhD

Prostacyclin, the labile prostanoid product of arachidonic acid metabolism in vascular endothelium, is the most potent known inhibitor of platelet aggregation and is highly effective in relaxing vascular smooth muscle. Its production is probably critically important in the maintenance of an intact vasculature. Although there is some evidence that prostacyclin circulates as a hormone, it is probably most important as a locally active agent in preventing thrombosis and maintaining patent vessels. Several factors can influence prostacyclin production, the most important of which probably act locally at sites of vessel wall injury. The mos promising therapeutic approaches toward usin prostacyclin's beneficial effects in vascular diseas may lie in the use of drugs aimed at increasin prostacyclin production. Among these are throm boxane synthesis inhibitors, which act by divertin prostaglandin endoperoxides through the prosta cyclin synthetase pathway, and lipoxygenase in hibitors, which might act chiefly by preventin formation of metabolites capable of inhibitin prostacyclin synthetase.

The discovery of thomboxane A_2 (TxA_2) as the most potent known promotor of platelet aggregation[1] focused attention on platelet arachidonic acid metabolites as major factors in the development of thrombi in blood vessels. Indeed, this provided the stimulus to the trials of antiplatelet drugs that began in the mid-1970s.[2] Their lack of conspicuous success suggests that thromboxane-mediated platelet aggregation is not the major contributor to coronary thrombus formation, and indicates that TxA_2 produced by platelets might not contribute substantially to coronary vasospasm and ischemia.[2]

The discovery of prostacyclin (PGI_2)[4] has altered fundamentally our understanding of these processes; this prostanoid may be a key factor in prevention of thrombosis and vasospasm by its actions as the most potent known inhibitor of platelet aggregation and as a potent vasodilator. PGI_2 was first recognized as a labile product of arachidonic acid metabolism, generated enzymatically by aortic microsomes from prostaglandi endoperoxides as substrate; it is an extremely poten inhibitor of platelet aggregation and is capable of re laxing vascular smooth muscle. From the very earlies experiments with this material, it appeared that PGI was an important factor in platelet-vessel wall inter actions.[5] For example, aortic microsomes added t platelet-rich plasma inhibited platelet aggregation,[6] a effect shown specifically to be a result of the generatio of PGI_2 from endoperoxides presumably supplied by th platelet. From this type of observation came the view that endothelial cells did indeed obtain their endo peroxides from platelets, and that generation of PGI by endothelial cells explained why platelets did no constantly aggregate when coming into contact wit vessel walls. The concept that endoperoxides from th platelets might be the sole substrate for endothelia PGI_2 synthesis has not been maintained, however, be cause it is clear that aortic and venous endothelial cell can produce PGI_2 in the absence of platelets.[8] Thus although under some circumstances platelet endo peroxides may contribute to endothelial PGI_2 forma tion, for the most part it seems likely that endothelia cells generate their own endoperoxides from arachidoni acid liberated from its esterified form in membran phospholipid.

Figure 1 illustrates the major pathways of cellula metabolism of arachidonic acid by way of the cycloox

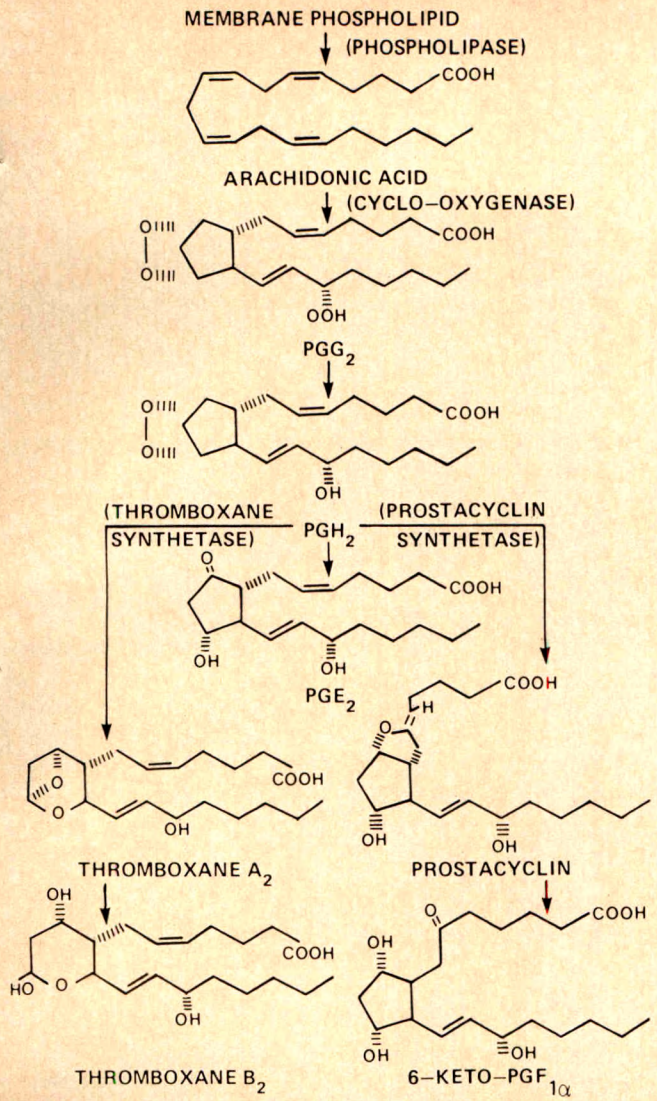

FIGURE 1. Pathways of metabolism of arachidonic acid via cyclooxygenase.

ygenase route. Control of the key enzymes in the pathways is crucial in determining the pattern of biologically active metabolites formed in individual tissues. These enzymes are regulated by levels of available substrates, the direct actions of other metabolites and of mediators such as cyclic nucleotides or calcium ions, or the indirect actions of external influences such as local or systemic hormones or vasoactive agents. Definition of the factors regulating PGI_2 production by endothelial cells is of considerable importance to our understanding of the mechanisms of thrombus formation and vascular spasm.

Actions of Prostacyclin and Thromboxane A_2

The actions of PGI_2 and TxA_2 that are relevant to their roles in cardiovascular physiology and disease are chiefly their opposing effects on blood platelets and vascular smooth muscle. TxA_2 is a potent inducer of platelet aggregation and secretion,[1] but the fact that prostaglandin endoperoxides themselves can probably induce platelet aggregation suggests that blockade of thromboxane production by platelets will not impair their ability to aggregate by mechanisms that involve arachidonic acid metabolism. The biochemical actions of thromboxane upon the platelet that are thought to mediate its aggregatory effect consist of an inhibition of platelet (cyclic AMP) production[9] and mobilization of calcium stores from within platelet granules. The antiaggregatory effect of PGI_2 requires for its initial action upon platelets the stimulation of adenylate cyclase.[10,11] Potentiation of the antiaggregatory action of PGI_2 by dipyridamole can be explained by inhibition of cyclic nucleotide phosphodiesterase activity.[12] The platelet process regulated by cyclic AMP probably include both inhibition of enzymatic liberation of arachidonate from platelet membranes, thus limiting formation of aggregatory endoperoxides and thromboxane, and inhibition of calcium release from platelet granules. The inhibition of aggregation by prostacyclin is achieved at much lower concentrations than those required to inhibit platelet adhesion,[13] allowing platelet involvement in vascular repair while preventing thrombus formation.

These opposing actions of PGI_2 and TxA_2, one favoring vascular patency and continuing blood flow and the other vascular constriction and thrombosis, were the basis of proposals[4,5,7] that a balance between production of the 2 was necessary for the maintenance of a healthy vasculature.

Prostacyclin and Thromboxane A_2 in Disease

Before PGI_2 was discovered and its importance realized, antithrombotic therapy was aimed at inhibiting TxA_2 production by using drugs to inhibit the cyclooxygenase enzyme. However, clinical effects were not striking; furthermore, prevention of TxA_2 production was associated with no more than a prolongation of bleeding time. Thus, the importance of TxA_2 as a major determinant in thrombotic states was questioned, particularly with increasing evidence of the production and action of PGI_2.

The view that PGI_2 production may be more important than TxA_2 production in determining spasm and ischemia is supported by recent clinical data. Thus, coronary sinus/aortic ratios of thromboxane B_2 (TxB_2) were found to be higher in patients with coronary artery disease and pain in the previous 24 hours than in those with more remote pain or without coronary artery disease.[14] On the other hand, in patients with vasotonic angina pectoris, the TxB_2 increase in coronary sinus blood associated with ischemia occurred well after the onset of ischemia.[15] Furthermore, indomethacin did not reduce the frequency or duration of angina. The likely interpretation of these observations may be that TxA_2 generation by platelets does not initiate large-vessel constriction. Thus, although increased amounts of TxB_2 have been found in peripheral blood[16] and coronary sinus blood[14] of patients with vasotonic angina, and in coronary sinus blood of patients with other forms of angina,[15] it is not possible to assess the extent of the contribution made by activated platelets. Alternatively, decreased PGI_2 production may be an important factor

in the development of vasospasm. It has been thought likely that the major source of PGI_2 for maintenance of coronary vascular tone is the coronary vascular endothelium[17]; however, recent investigations suggest that pericardial fluid PGI_2, produced by the visceral and parietal pericardium, might contribute to the maintenance of coronary vascular tone, at least in the large, superficial coronary vessels.[18] Maintenance of normal PGI_2 production in or near vessels may be essential for the prevention of thrombosis and the regulation of vascular tone.

Experimental evidence in rabbits[19] and some data in man[20] indicate that atherosclerotic vessels have a reduced capacity to produce PGI_2, a phenomenon that could result from the effect of the lipid peroxides of atherosclerotic plaques that[21] inhibit PGI_2 production.[22] Disease states in man in which increased sensitivity to platelet-aggregating agents and increased production of TxA_2 by platelets are observed presumably result from a shift of endoperoxides toward thromboxane production; this may be the result primarily of prostacyclin deficiency. Such a mechanism may indeed operate in some forms of diabetic vascular disease. Aortas of diabetic rats produce less PGI_2 in vitro than do aortas of control rats; this deficiency can be prevented or corrected by insulin treatment.[23] Similar observations have been made by others in experimental diabetes[24]; furthermore, incubations of human diabetic vessels have provided results consistent with this finding.[25] Isolated glomeruli prepared from diabetic rats do not show the same deficient PGI_2 production as do large vessels,[26] suggesting that PGI_2 deficiency might be a feature of the large-vessel rather than of the small-vessel disease of diabetes. Indeed, the demonstration of certain differences between the behavior of endothelial cells of macrovascular and microvascular origin[27] indicates that we should not conclude that the processes controlling PGI_2 production are identical in the 2 types of vessel. It is important, therefore, to understand the mechanisms that regulate PGI_2 formation by endothelial cells of large and small vessels, and perhaps also by the pericardium if peri cardial PGI_2 contributes to maintenance of coronar vascular tone.

Regulation of Prostacyclin Production

The factors that can influence PGI_2 production ma be circulating or local. Angiotensin II increases PGI production upon infusion into rat mesenteric ves sels.[28,29] The peptide produces this effect by promotin release of arachidonic acid from membrane phospho lipid,[29] in a manner similar to the action of bradykinin.[3] In studying the action of angiotensin II in the isolate vasculature, we noted a selective increase in PGI_2 re lease (Fig. 2), suggesting either that mesenteric vascula endothelium is particularly rich in PGI_2 synthetase o that the enzyme is closely coupled to cyclooxygenase i those cells. If this action of angiotensin II is physiolog ically important, the peptide may act as a local rathe than as a circulating hormone. Certainly, bradykini and related substances are regarded as locally activ agents. Moreover, most of the other endogenous factor capable of stimulating PGI_2 production appear mor likely to act as local rather than as systemic effectors This applies to thrombin,[31] histamine[32] and platelet derived growth factor, the major protein constituent o the platelet that stimulates PGI_2 production.[33] Indeed local events may be more important than circulatin factors in the regulation of vascular PGI_2 production

Systemic hormonal regulation of PGI_2 productio would be easier to accept if it were firmly establishe that the prostanoid circulates as a hormone. This is however, an area of some dispute. There is biologic assay

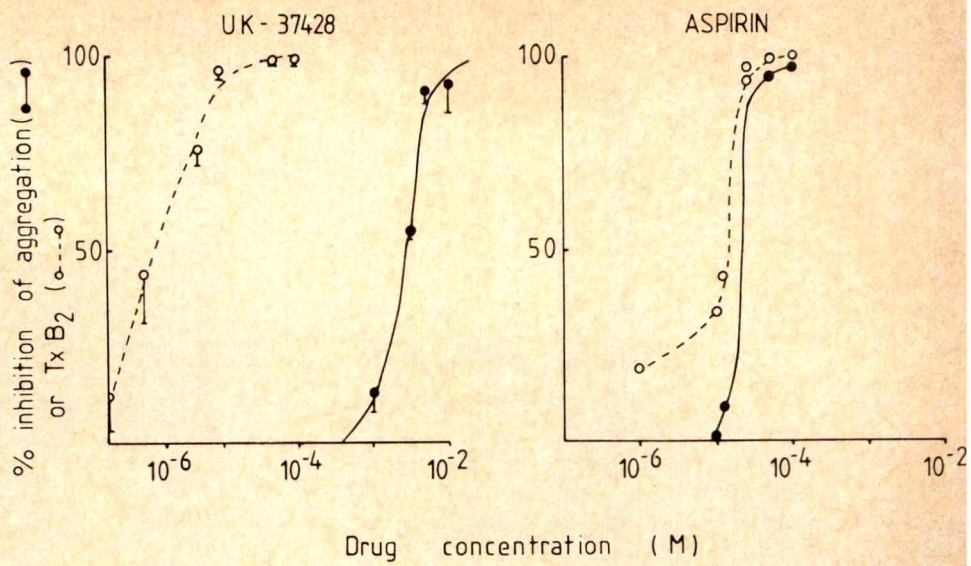

FIGURE 3. Effects of dazoxiben (UK-37,248) and aspirin on platelet aggregation and thromboxane B_2 (TxB_2) production. Each drug was incubated at the indicated concentrations with human platelet-rich plasma, and aggregation responses and TxB_2 production were measured after 5 minutes of incubation with 0.8 m*M* arachidonic acid. Results are expressed as percent inhibition of aggregation (**closed circles**) or of TxB_2 production (**open circles**). Methods used in these experiments have been published.[44] Dazoxiben (UK-37,248) was provided by Dr. H. A. M. Tyler, Pfizer Central Research, Sandwich, Kent, United Kingdom.

evidence that PGI_2 does circulate[35,36]; furthermore, whereas the lungs rapidly inactivate other prostanoids, they do not do so to PGI_2.[36] However, the conclusion that PGI_2 is a systemic hormone circulating in effective concentrations is seriously questioned by the data of Haslam and McClenaghan,[37] who used a very sensitive bioassay to show that fresh arterial blood from normal rabbits contains insufficient PGI_2 or 6-keto-$PGF_{1\alpha}$ to affect platelet function.

Among the local determinants of PGI_2 production are cyclic nucleotides and other products of arachidonate metabolism, amounts of any of which could be influenced by circulating factors. Thus, endothelial cell cyclic AMP is increased by isoproterenol and by PGI_2 itself[38–40] (Table I). The increase in cyclic AMP can inhibit phospholipase activity and regulate formation of PGI_2 within the endothelial cells[40] (Table II). This constitutes an autoregulatory system by which endothelial cell PGI_2 can regulate its own production. Furthermore, beta-adrenergic agonists can similarly modulate PGI_2 production. Although beta-adrenergic blocking drugs prevent this response directly,[40] whether they can influence PGI_2 production by vascular endothelium in vivo is not known.

The sensitivity of PGI_2 synthetase to inactivation by hydroperoxy-fatty acids[22,41,42] suggests that products of the lipoxygenase pathway of arachidonate metabolism play a regulatory role in the normal or pathologic production of PGI_2.

Undoubtedly, several other important control processes regulate PGI_2 formation, and various combinations of these operate during tissue damage. Thus, when vascular injury takes place, the local event of injury would result in stimulation of adjacent endothelial cells to produce PGI_2. The actual stimuli to PGI_2 production in such circumstances could be several, including thrombin and platelet-derived growth factor. Increased levels of PGI_2 might result from stimulation of enzymes directly in the pathway of arachidonate metabolism or from removal of inhibitory influences, such as lipoxygenase products. In atherosclerosis and diabetes, the disease process appears to result in a decreased PGI_2 production, thus favoring the formation of thrombi; under these circumstances, platelet-generated TxA_2 might contribute the development of vascular spasm.

Considering platelet-vessel wall interactions in this way, we see a system in which the tendency is toward thrombosis—a tendency overcome by the constant production of an antithrombotic vasodilator substance (PGI_2). At times of extra stress, for example, in vessel wall injury, this substance is produced in increased amounts; in certain disease states, decreased PGI_2 production favors thrombus formation.

Alteration of Prostacyclin Production by Drugs

With the knowledge of PGI_2 actions and the regulation of its production, the main goal in prevention and treatment of thrombotic diseases is to achieve a high PGI_2 activity at sites predisposed either to thrombosis or vascular spasm. PGI_2 has been reported to relieve ischemic pain and heal ulcers after intraarterial infusion for 3 days in patients with peripheral vascular disease.[43,44] However, the need for prolonged infusion and the hypotensive effect may present difficulties in treating patients directly with PGI_2, even if satisfactory stable analogs were developed. A more promising approach might be to use drugs that increase PGI_2 production. This approach will require a detailed understanding of the control of PGI_2 formation.

The 2 main principles operating with current drugs are: (1) that inhibition of TxA_2 production could divert endoperoxides to the synthesis of PGI_2, and (2) that inhibition of lipoxygenase activity could prevent formation of a substance capable of inhibiting PGI_2 production.

Thromboxane synthetase inhibitors are being studied because they have the advantage over cyclooxygenase inhibitors of allowing endoperoxides to accumulate and of increasing PGI_2 production. A difficulty arises because at higher doses, these drugs can inhibit cycloox

TABLE III Effect of Dazoxiben (UK-37,248) Upon 6-keto-$PGF_{1\alpha}$ Production by Bovine Aortic Endothelial Cells

ygenase activity. An example is illustrated in Figure 3, in which the thromboxane synthetase inhibitor dazoxiben (UK-37,248)[46,47] prevents platelet aggregation. At some concentrations of the drug, although inhibition of thromboxane synthesis is complete, platelet aggregation with arachidonic acid was unaffected, probably because of the direct aggregatory effect of the prostaglandin endoperoxide. At higher drug concentrations, arachidonate-induced aggregation was prevented, probably because endoperoxide formation was inhibited. Thus, a certain dose range existed over which thromboxane synthesis inhibition was achieved, but above that, cyclooxygenase was inhibited. The very narrow dose range of effectiveness of aspirin is shown for comparison. In studying the effect of dazoxiben on collagen-induced platelet aggregation, the 50% inhibition (IC_{50}) for the drug was 5×10^{-6} *M*,[47] similar to that for inhibition of TxB_2 production (Fig. 3).

Furthermore, in studies with cultured bovine aortic endothelial cells, the thromboxane synthesis inhibitor dazoxiben caused an increase in PGI_2 production, but high concentrations (10^{-3} *M*) reduced PGI_2 production (Table III). Such data might indicate that endoperoxide in endothelial cells can be diverted from synthesis of TxA_2 to PGI_2. Indeed, there is evidence for production of TxA_2 in cultured calf aortic endothelial cells[48] and from our own observations (Nolan RD and Martin TJ, unpublished data) with bovine aortic endothelial cells. If TxA_2 synthesis inhibition is to be applied optimally, the properties of the drugs must be examined relative to their selectivity as thromboxane synthesis inhibitors and the practical ease with which cyclooxygenase inhibition can be avoided. This will probably be achieved and part of a pharmacologic approach to the prevention of vascular occlusion will be thromboxane synthesis inhibition.

Lipoxygenase inhibition applies different principles in aiming at increased PGI_2 production. There is increasing evidence that products of the lipoxygenase pathway can inhibit PGI_2 production,[22,42,42] and it is logical to seek lipoxygenase inhibitors for the specific purpose of increasing PGI_2 formation. Again, the problem of cyclooxygenase inhibition arises, and it may be very difficult to find a lipoxygenase inhibitor that is not also a cyclooxygenase inhibitor. Nafazatrom (Bay g 6575) is an effective inhibitor of lipoxygenase. It has no direct effects on platelets, but has been shown to elevate the PGI_2 production of diabetic blood vessel in vitro.[49] Determining whether this will be of therapeutic benefit requires careful evaluation, but the observation raises interesting questions regarding the mechanisms of decreased PGI_2 production in diabetes.

Prostacyclin Produced by the Pericardium and Its Influence on Coronary Vascular Tone

GREGORY J. DUSTING, PhD, BSc, ROGER D. NOLAN, BSc,
OWEN L. WOODMAN, PhD, BSc, and T. JOHN MARTIN MD, DSc

To determine the influence of pericardial fluid prostacyclin on coronary blood flow, the latter was measured in the circumflex artery of anesthetized dogs. Intraaortic infusions of angiotensin II (25 ng·kg^{-1}·min^{-1}) reduced blood flow and released prostacyclin into pericardial fluid. Epicardial and pericardial superfusion with indomethacin (1 μg/ml) abolished prostacyclin release and significantly increased the coronary vasoconstrictor effect of angiotensin II; this treatment did not appear to affect vascular synthesis of prostacyclin. Pericardial prostacyclin may modulate the coronary vasoconstrictor effect of angiotensin, but its general role as a regulator of coronary vascular resistance is probably limited. A more important effect of pericardial prostacyclin may be exerted on the large coronary vessels in the epicardial surface. Release of prostacyclin into pericardial fluid represents a potential mechanism for opposing coronary vasospasm, especially if platelet activation is found to be a contributory factor in vasotonic angina pectoris.

Although it has long been known that the heart can produce prostanoids,[1,2] until recently the coronary vasculature was considered the only important local site of prostanoid biosynthesis.[3] However, some recent evidence has revealed the production of PGE_2 and $PGF_{2\alpha}$ by isolated cardiac myocytes, whereas PGE_2, $PGF_{2\alpha}$ and prostacyclin (PGI_2) may be produced by cardiac mesenchymal cells.[4,5] The role of cardiac prostanoids in function of the normal and ischemic heart has not been clearly resolved despite intensive investigation.[1,2]

In 1979, Herman et al[6] found that the pericardium and other serous membranes that are lined with mesothelium spontaneously generate a prostacyclin-like substance in vitro. They reported that mesothelial cells are derived from the same stem cells (the mesenchyme) as vascular endothelial cells, an important source of prostacyclin in the blood vessel wall.[7] We became interested in this potential source of prostacyclin because Dusting et al[8] had shown that topical application of prostacyclin to the left ventricular epicardium increases coronary blood flow. Moreover, prostacyclin and PGE_2 applied epicardially in low doses, potentiate a nociceptive pressor chemoreflex elicited from the epicardium in anesthetized dogs.[9,10] In this report, we review the evidence that the parietal pericardium and epicardial surface (containing visceral pericardium) are major producers of prostacyclin in vivo, and that the output of prostacyclin into pericardial fluid is increased by increasing cardiac work load.[11] We further show that pericardial production of prostacyclin is sufficient to influence coronary blood flow under some circumstances, but its most important effect may be to oppose vasoconstrictor influences on the large coronary vessels in the epicardial surface, because these vessels are normally in contact with pericardial fluid.

Methods

Incubation of pericardium and heart slices: Samples of bovine pericardium were obtained immediately after slaughter, transported to the laboratory in cold Krebs' solution, and processed within 2 hours. Dog and rat pericardial samples were treated similarly after killing the animals. Pieces of parietal pericardium from dog, ox and rat were incubated in Krebs' solution at 22°C for 60 minutes in the presence of arachidonic acid (10 μg/ml). Dog and ox pericardium were also incubated without arachidonic acid.

Slices (0.5 to 1.0 mm) of dog hearts were prepared using a Stadie-Riggs microtome. The slices were preincubated for 60 minutes at 22°C in Krebs' solution before experimental incubations were begun. Slices of epicardium (which included

visceral pericardium), myocardium and endocardium and pieces of parietal pericardium were incubated in Krebs' solution at 22° for 60 minutes in the presence of arachidonic acid (1 μg/ml). Zero time incubation samples were taken immediately after addition of tissue.

Anesthetized dog experiments: Mongrel dogs and greyhounds (10 to 35 kg) were anesthetized with thiopental (25 to 30 mg/kg, intravenously) followed by alpha-chloralose (80 to 100 mg/kg, intravenously) as required. Dogs were artificially ventilated with air that contained additional oxygen to maintain arterial blood pH and gases in the following ranges: pH 7.25 to 7.36, oxygen partial pressure 150 to 225 mm Hg, carbon dioxide partial pressure 25 to 37 mm Hg. Arterial pressure was measured from a catheter in a femoral artery and heart rate was determined by the pulse interval using a cardiotachometer coupler. The chest was opened in the fifth intercostal space and the pericardium was opened into a cradle, with care taken to minimize leakage of blood into the pericardial sac. Drugs were infused into a femoral vein and into the epicardial irrigating fluid (see below). Coronary blood flow was measured in the circumflex branch of the left coronary artery of greyhounds using a Statham electromagnetic flow probe (2.0 to 2.5 mm) and flowmeter (SP 2202). A catheter, introduced for infusions of drugs into the coronary circulation, was passed retrogradely down the right carotid artery so that its tip lay in the aortic root. All recordings were made on a Grass model 7 polygraph.

Epicardial irrigation: In most dogs, the left ventricular epicardium was irrigated in situ at 3 ml/min with warmed (37°C) oxygenated Krebs' solution as described previously.[11] The fluid was continuously withdrawn from the pericardial cradle beneath the heart and passed over bioassay tissues.[11] Alternatively, samples of this fluid were taken for analysis into tubes that contained indomethacin (10 μg/ml), kept at room temperature for 60 minutes, and then stored frozen until extraction.

Measurement of arachidonic acid metabolites: Irrigation fluid from the dog hearts and the media from the incubations of dog, ox and rat pericardium were acidified to pH 3.5 with 1 *M* formic acid and extracted with 3 volumes of ethyl acetate. The organic layer was evaporated under nitrogen at 30°C and resuspended in column solvent for high-pressure liquid chromatography as described previously.[12] Fractions of 2 ml were collected, lyophilized and assayed by radioimmunoassay for 6-oxo-$PGF_{1\alpha}$, thromboxane B_2 (TxB_2), $PGF_{2\alpha}$ and PGE_2. Recoveries of added [^{3}H] 6-oxo-$PGF_{1\alpha}$, [^{3}H] TxB_2, [^{3}H] $PGF_{2\alpha}$ and [^{3}H] PGE_2 were monitored and data were corrected for the average loss. Recoveries were 57 ± 2, 72 ± 7, 60 ± 6 and 53 ± 2% (mean ± standard error of the mean [SEM], n = 5) for 6-oxo-$PGF_{1\alpha}$, TxB_2, $PGF_{2\alpha}$ and PGE_2, respectively. In no case did the acidification and extraction procedure generate radioactivity with chromatographic behavior other than that of the authentic prostanoid.

The 6-oxo-$PGF_{1\alpha}$ and PGE_2 levels in the medium from incubation of slices of canine heart were determined by direct radioimmunoassay of the medium without separation by high-pressure liquid chromatography.

Radioimmunoassay: Fractions corresponding to the elution volumes of each of the 4 tritiated prostanoid markers were resuspended in Tris-gelatin buffer (15 m*M* Tris-hydrochloride, 140 m*M* sodium chloride, gelatin 500 mg/liter, pH 7.4) and analyzed by radioimmunoassay as described previously.[12] Samples analyzed by direct radioimmunoassay were assayed in Krebs' solution with a standard curve diluted in Krebs solution. Sensitivities and cross-reactivities of the assays have been reported in detail.[12]

Materials: Prostaglandins and their metabolites were gifts from Dr. J. E. Pike of the Upjohn Co. Arachidonic acid (Sigma grade 1) was stored in n-hexane (10 mg/ml) under nitrogen at −20°C. Immediately before use the solvent was evaporated under nitrogen and the arachidonic acid dissolved in 0.1 *M*

TABLE I Metabolites of Arachidonic Acid Produced by Dog, Ox and Rat Pericardium In Vitro

Species	Treatment	Metabolites (ng/100 mg of Tissue) 6-oxo-$PGF_{1\alpha}$	TxB_2	$PGF_{2\alpha}$	PGE_2
Dog	Basal AA	10.6	1.3	0.8	0.2
		112.3	7.2	15.8	58.6
Ox	Basal AA	0.8	<0.1	*	0.4
		25.0	2.1	*	23.8
Rat	AA	5.8	<0.1	*	0.3

* Assay not done.

Pieces of dog pericardium (500 mg in 12 ml), ox pericardium (330 mg in 2 ml) and rat pericardium (20 mg in 1 ml) were incubated at 22°C in Krebs' solution for 60 minutes. Amounts of arachidonic acid metabolites in the Krebs' solution were determined by radioimmunoassay after separation by high-pressure liquid chromatography.

AA = arachidonic acid (10 μg/ml); PG = prostaglandin; TxB_2 = thromboxane B_2.

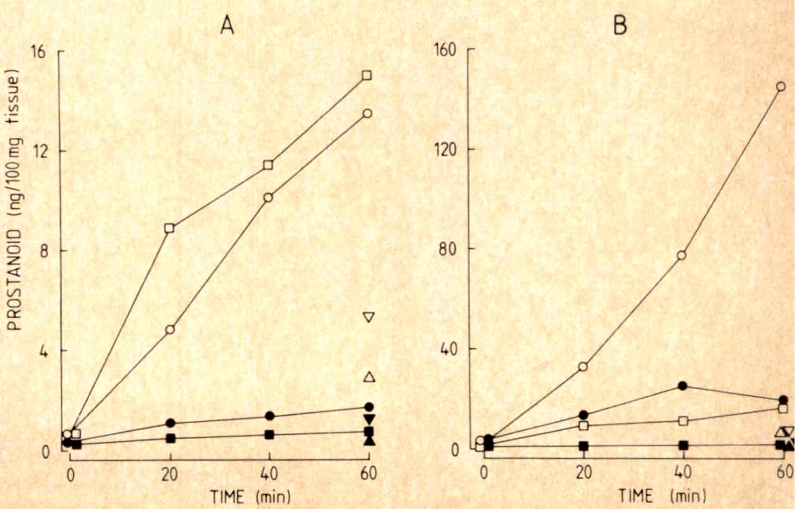

FIGURE 1. The 6-oxo-prostaglandin $F_{1\alpha}$ (**open symbols**) and prostaglandin E_2 (**closed symbols**) produced by the parietal pericardium (**circles**), epicardium (**squares**), myocardium (**triangles**) and endocardium (**inverted triangles**) of dog heart. Pieces of parietal pericardium and slices (0.5 to 1.0 mm, approximately 100 mg) of each layer of the heart were incubated at 22°C for 60 minutes in Krebs' solution. **A,** Incubation in Krebs' solution alone. **B,** Incubation in Krebs' solution containing arachidonic acid (1 μg/ml). The sensitivities of the radioimmunoassays were 1.0 and 10 pg/mg tissue for 6-oxo-$PGF_{1\alpha}$ and prostaglandin E_2, respectively.

sodium carbonate, making the sodium salt. Indomethacin (Sigma) was dissolved in 1 *M* Tris buffer (pH 8.4). Isoproterenol (Isuprel,® Winthrop) and angiotensin II (Hypertensin,® Ciba) were diluted in 0.9% (weight/volume) sodium chloride immediately before use.

Antibodies used were diluted rabbit antiserum directed against PGE_2, $PGF_{2\alpha}$ and 6-oxo-$PGF_{1\alpha}$.

Results

Prostacyclin produced by the pericardium and cardiac slices in vitro: Pieces of parietal pericardium from dog, ox and rat were incubated in Krebs' solution at 22°C with and without arachidonic acid (10 μg/ml), and prostanoids released into the incubation medium were measured by radioimmunoassay after extraction and chromatography (Table I). The hydration product of prostacyclin 6-oxo-$PGF_{1\alpha}$, was the major product detected in all species, although large amounts of PGE_2 were also produced in the presence of arachidonic acid.

The rate of prostacyclin production by the pericardium of the dog was compared with that of cardiac slices by direct radioimmunoassay of 6-oxo-$PGF_{1\alpha}$ released into the incubation medium. Pieces of parietal pericardium and slices of epicardium, myocardium and endocardium were incubated with or without added arachidonic acid (1 μg/ml) (Fig. 1). The parietal pericardium and epicardium were the most active producers of 6-oxo-$PGF_{1\alpha}$, producing more than 12 ng/100 mg of tissue after 60 minutes of incubation. Less than 2 ng of PGE_2/100 mg of tissue were produced by all tissues during these incubations. Addition of arachidonic aci greatly increased the formation of 6-oxo-$PGF_{1\alpha}$ an PGE_2 by the pericardium, but did not appreciably alte prostanoid formation by the other tissues (Fig. 1B).

Epicardial and pericardial irrigation of the dog heart in situ: Prostacyclin production has also bee studied in vivo by irrigating the left ventricular epi cardium and pericardium of the dogs' heart in situ.[1] The fluid was continuously withdrawn from the peri cardial cradle beneath the heart and either used directl to superfuse the bioassay tissues, or taken into tube containing indomethacin (10 μg/ml) for subsequen extraction, chromatography and radioimmunoassay When the fluid superfusing the bioassay tissues wa changed from fresh Krebs' solution to one that had firs irrigated the epicardium and pericardium, the bioassa tissues responded in a manner consistent with th presence of prostacyclin in the superfusate, equivalen to 2 to 10 ng/ml (Fig. 2). Epicardial irrigation wit Krebs' solution did not affect arterial pressure or hear rate. After 15 to 50 minutes of continuous epicardia irrigation, the tone of the bioassay tissues superfuse with this solution had returned to or near their base lines, suggesting that the release of the prostacyclin-lik substance from the epicardial surface had diminished Handling the heart in the pericardium when the initial effects of irrigation has subsided caused a further burst of release of the prostacyclin-like substance.

After the initial effects of epicardial irrigation had subsided, arachidonic acid (3 μg/ml) was added to the

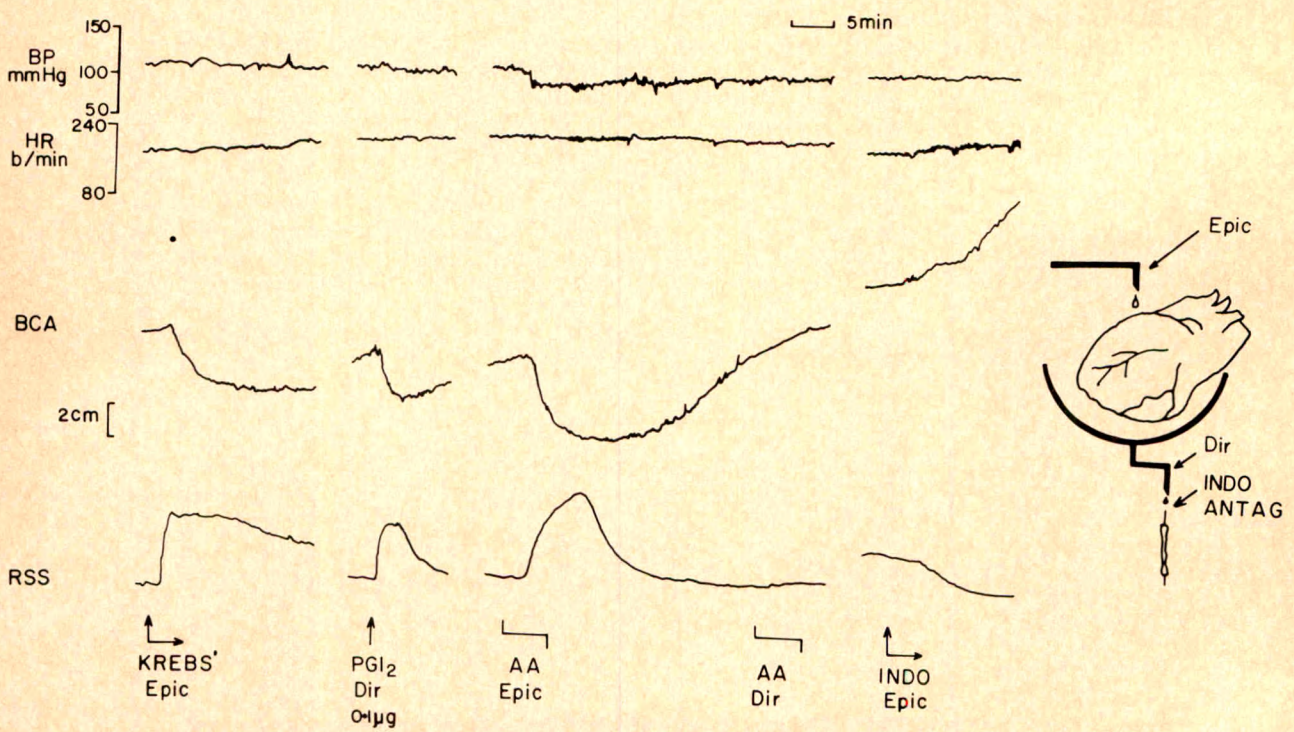

FIGURE 2. Epicardial and pericardial irrigation of a dog's heart with Krebs' solution. The records of a typical experiment are arterial blood pressure (BP), heart rate (HR) and tone of strips of bovine coronary artery (BCA) and rat stomach superfused with the irrigation fluid (RSS; see text). **Left,** the reactions of the bioassay tissues when they were superfused with Krebs' solution that had first irrigated the heart; superfusion was maintained for the rest of the experiment. The record shows the effects of addition of arachidonic acid (AA) (3 μg/ml) and indomethacin (INDO) (1 μg/ml) for the periods indicated beneath the records. Substances are added to the epicardial fluid as indicated by the diagram on the **right.** Dir = direct; Epic = epicardial; PGI_2 = prostacyclin. TABLE II Metabolites of Arachidonic Acid in the Epicardial Irrigation Fluid From Dog Heart

Sample	Arachidonic Acid Metabolites (ng/ml)			
	6-oxo-$PGF_{1\alpha}$	TxB_2	$PGF_{2\alpha}$	PGE_2
Initial sample (a)	5.6	1.6	0.5	0.5
Control isoproterenol (b)	2.8	0.7	0.1	0.8
	7.3	<0.2	0.5	0.2
Control arachidonic acid (b)	0.3	<0.2	0.1	0.2
	3.5	1.0	0.6	1.4

Samples of epicardial irrigation fluid (15 ml) were collected (a) during the first 5 minutes of irrigation (initial sample); (b) before and during intravenous infusion of isoproterenol (0.1 μg/kg/min) for 5 minutes; and (c) before and during addition of arachidonic acid (3 μg/ml) for 5 minutes to the irrigating fluid. Test samples were collected over 5 minutes, commencing 1 minute after the start of each treatment. Sixty minutes elapsed between experimental periods a, b and c. Concentrations of metabolites were determined by radioimmunoassay after separation by high-pressure liquid chromatography.
PG = prostaglandin; TxB_2 = thromboxane B_2.

irrigation fluid for 5 minutes. This reduced arterial pressure by 5 to 18 mm Hg and increased heart rate by 14 to 18 beats/min; the bioassay tissues indicated, within 1 to 3 minutes, the output of a prostacyclin-like substance[11] equivalent to >100 ng of standard prostacyclin (Fig. 2). The same concentration of arachidonic acid had no effect on the bioassay tissues when infused directly over them (Fig. 2). When arachidonic acid was added to the epicardial irrigating fluid in 2 dogs previously treated with indomethacin (10 mg/kg, intravenously), there were no effects on blood pressure, heart rate or the bioassay tissues.

After 2 to 4 hours of epicardial irrigation, indomethacin (1 μg/ml) was added to the irrigation fluid. In all experiments, this induced within 5 to 10 minutes an increase in tone of the bovine coronary artery and relaxation of the rat stomach strip (Fig. 2), but had little effect on the rat colon. Relaxation of the bovine artery induced by standard bolus doses of prostacyclin (25 to 100 ng) increased after treating the heart with indomethacin. These observations suggested that epicardial treatment with this cyclooxygenase inhibitor had prevented the release of prostacyclin into the irrigation fluid.[11]

Stimuli that increase prostacyclin release into pericardial fluid: Some maneuvers that alter systemic blood pressure or heart rate in the dog also increase release of the prostacyclin-like substance in vivo.[11] For example, intravenous infusions of isoproterenol (0.1 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 5 minutes), which increased heart rate by 33 ± 5 beats/min and reduced mean arterial pressure by 18 ± 2 mm Hg (mean ± SEM, n = 8), increased release of the prostacyclin-like substance into the epicardial irrigating fluid, equivalent to 50 to 100 ng of prostacyclin (Fig. 3). Addition of indomethacin (1 μg/ml) to the irrigating fluid abolished release of the substance (Fig. 3), as did intravenous propranolol (0.5 mg/kg). Radioimmunoassay confirmed that prostacy-

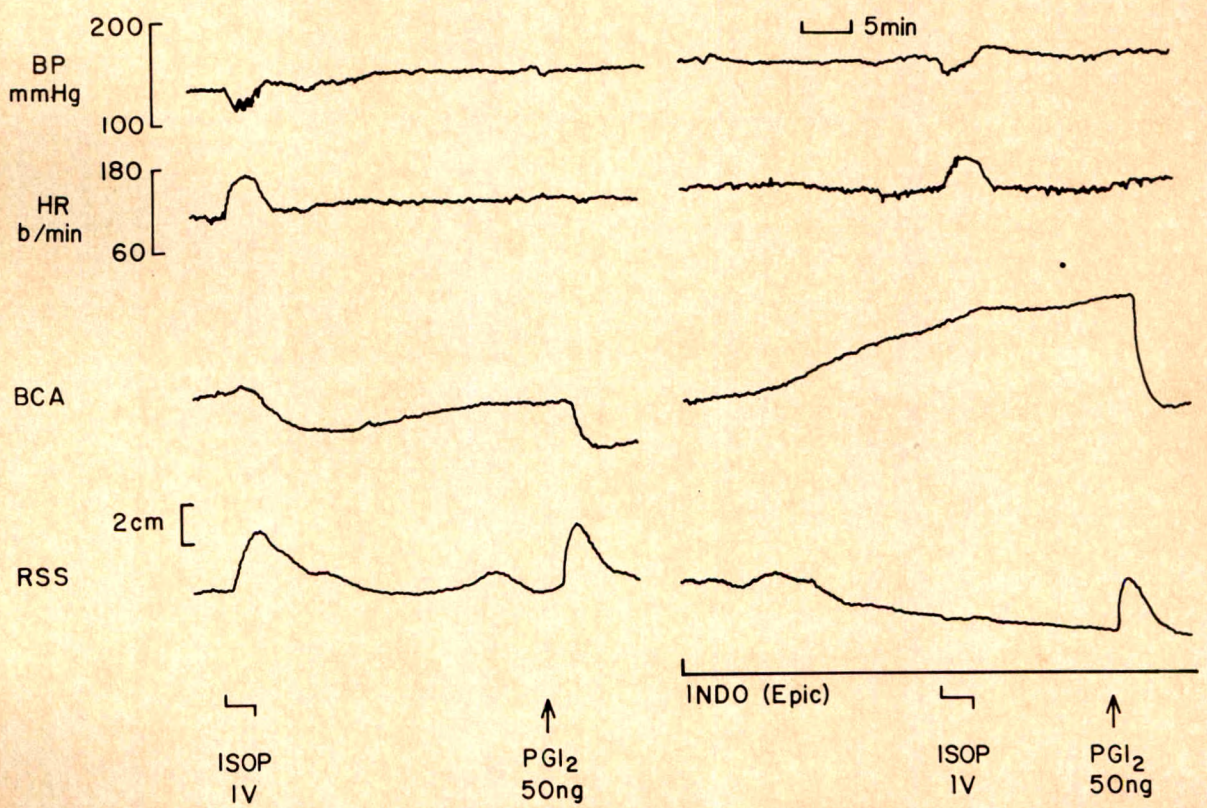

FIGURE 3. Effect of intravenous infusions of isoprenaline (ISOP) (0.1 $\mu g \cdot kg^{-1} \cdot min^{-1}$) on output of the prostacyclin (PGI_2)-like substance into the epicardial irrigation fluid. Records are as in Figure 2. In the **second panel,** epicardial indomethacin (INDO Epic) (1 μg/ml) is superfused over the heart instead of directly over the bioassay tissues. BCA = bovine coronary artery; BP = blood pressure; Dir = direct; Epic = epicardial; HR = heart rate; INDO = indomethacin; RSS = rat stomach strip. TABLE III Effects of Angiotensin Infusions on Coronary Blood Flow After Indomethacin

	Control		Epicardial Indomethacin		Intravenous Indomethacin	
	Resting	AII Response* (%)	Resting	AII Response* (%)	Resting	AII Response* (%)
mBP (mm Hg)	132 ± 6	23 ± 6	135 ± 7	21 ± 5	149 ± 14†	16 ± 9
mCBF (ml/min)	89 ± 17	−3 ± 5	87 ± 15	−12 ± 4†	69 ± 7	−19 ± 7†

* Responses measured as percentage of resting blood pressure and coronary blood flow in each case.
† Significantly different from control values ($p < 0.05$ paired Student t test).
Angiotensin II was infused in 5 dogs intraarterially at 25 $ng \cdot kg^{-1} \cdot min^{-1}$ during a control period, during epicardial superfusion with indomethaci (1 $\mu g/ml$) and in 3 of these dogs after intravenous indomethacin (5 mg/kg). Values are mean ± standard error of the mean.
AII = angiotensin II; mBP = mean arterial blood pressure; mCBF = mean coronary blood flow.

clin, measured as 6-oxo-$PGF_{1\alpha}$, was the major, if not the only, prostanoid released into the epicardial fluid by stimulation with isoproterenol (Table II).

The effects of isoproterenol may have been a result of its action on heart rate, because in 5 dogs whose heart rates were controlled by right atrial pacing, increasing the rate abruptly by 60 to 90 beats/min also released the prostacyclin-like substance, equivalent to 50 to 100 ng of prostacyclin. However, stimuli that increase afterload have also been found to release this substance, including aortic constriction, angiotensin infusions (0.02 to 0.1 $\mu g \cdot kg^{-1} \cdot min^{-1}$, intravenously), and bilateral carotid occlusion.[11] All of these stimuli increase cardiac work (calculated as mean arterial pressure/heart rate product) and cause increased stretching of the pericardium and epicardium. Intravenous indomethacin (5 to 10 mg/kg) and aspirin (50 mg/kg) also abolished release o the prostacyclin-like substance.[11]

Chromatography and radioimmunoassay of un diluted pericardial fluid and epicardial irrigatio fluid: Approximately 2 ml of pericardial fluid could b withdrawn from dogs immediately after opening th pericardial sac. The concentrations of all prostanoid in pericardial fluid showed wide variation between in dividual dogs, but 6-oxo-$PGF_{1\alpha}$ was always the pre dominant prostanoid detected. The concentrations o this prostanoid ranged from 1 to >30 ng/ml, as deter mined by radioimmunoassay after extraction anc chromatography. The mean concentrations of 6-oxo $PGF_{1\alpha}$, PGE_2, $PGF_{2\alpha}$ and TxB_2 in pericardial fluid o 8 dogs were 5.9 ± 2.8, 0.18 ± 0.14, 0.18 ± 0.11 and 0.2 ± 0.22 ng/ml (± SEM), respectively.

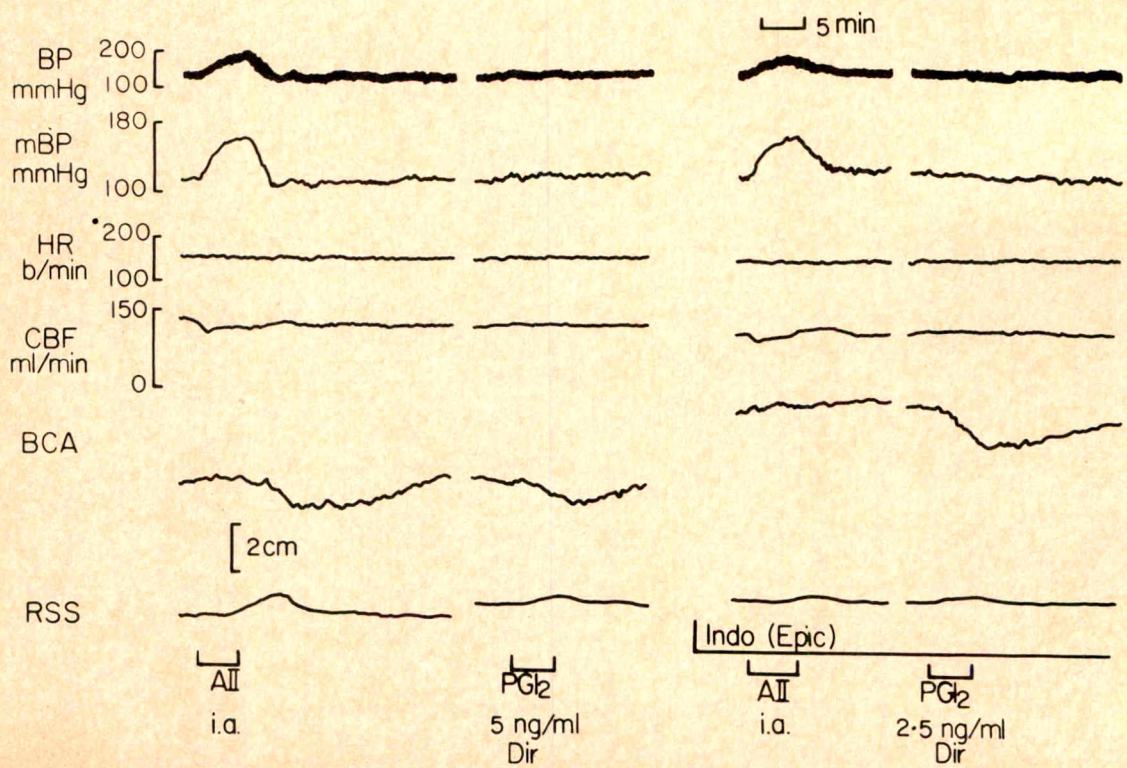

FIGURE 4. Effect of epicardial indomethacin (Indo Epic) (1 $\mu g/ml$) on the coronary blood flow (CBF) and release of the prostacyclin (PGI_2)-like substance induced by intraaortic angiotensin II (AII) (25 $ng \cdot kg^{-1} \cdot min^{-1}$) in an anesthetized dog. Records are as in Figure 2 with the addition of phasic blood pressure (BP) and blood flow in the circumflex artery, measured with a 2.0-mm electromagnetic probe. BCA = bovine coronary artery; Dir = direct; HR = heart rate; i.a. = intraaortic; mBP = mean BP; RSS = rat stomach strip.

Samples of epicardial irrigation fluid collected during the first 5 minutes of irrigation contained more 6-oxo-$PGF_{1\alpha}$ than the total amount of PGE_2, $PGF_{2\alpha}$ and TxB_2, as measured by radioimmunoassay (Table II). After 120 minutes of epicardial and pericardial irrigation, addition of arachidonic acid to the irrigating fluid increased the release of all prostanoids, although 6-oxo-$PGF_{1\alpha}$ remained predominant (Table II).

Pericardial prostacyclin and coronary blood flow: Infusions of angiotensin II (0.025 $\mu g \cdot kg^{-1} \cdot min^{-1}$ for 5 minutes) into the aortic root increased arterial pressure, reduced heart rate, and released a prostacyclin-like substance into epicardial irrigation fluid. Coronary blood flow, measured in the circumflex artery, was reduced slightly in most dogs (Fig. 4). The mean increases in arterial pressure and changes in mean blood flow at the end of the infusion periods are shown in Table III. Epicardial and pericardial superfusion with indomethacin (1 μg/ml) did not change resting arterial pressure or blood flow, but abolished angiotensin-induced release of prostacyclin (Fig. 4) and significantly increased ($p < 0.05$, paired Student t test) the coronary vasoconstrictor response (Table III). After intravenous infusion of indomethacin (5 mg/kg), the decrease in coronary blood flow induced by angiotensin was also greater than that in the control period, but the pressor response was not changed (Table III).

The effect of indomethacin on coronary blood flow responses to arachidonic acid was also studied. Intraaortic injections of arachidonic acid (100 μg/kg) caused rapid, transient increases of blood flow followed by hypotension and tachycardia (Fig. 5). In only 3 of 10 dogs was there any indication of prostanoid release into the pericardial irrigation fluid; this amounted to <50 ng of standard prostacyclin. Epicardial superfusion with indomethacin (1 μg/ml) did not significantly alter the coronary vasodilator or hypotensive effect of arachidonic acid, but intravenous indomethacin (5 mg/kg) greatly reduced the flow response and abolished the hypotension (Fig. 5).

Discussion

Source of prostacyclin in pericardial fluid: Microsomes of myocardium are much weaker producers of prostaglandins[13–15] than those of blood vessels.[16] Moreover, prostacyclin is the major metabolite of arachidonic acid released both from isolated coronary arteries and from Langendorff-perfused hearts.[17–20] Thus, Sivakoff et al[3] concluded that the coronary vasculature, rather than myocytes, was the primary site of cardiac prostaglandin synthesis. We have clearly shown that high concentrations of a prostacyclin-like substance and 6-oxo-$PGF_{1\alpha}$ (the degradation product of prostacyclin) are released into pericardial fluid in vivo, and only much smaller amounts of other prostanoids can be detected. However, several pieces of evidence suggest that the coronary vasculature is not a major source of pericardial fluid prostacyclin. First, epicardial and pericardial superfusion with indomethacin abolished the release of prostacyclin into the irrigation fluid. However, this treatment did not alter the coronary vasodilator effects of arachidonic acid administered into the vascular compartment, suggesting that the inhibitor did not penetrate to the cyclooxygenase in the coronary vasculature. Second, intravenous infusions of prostacyclin at rates achieving supraphysiologic concentrations in the bloodstream were not accompanied by detectable increases of prostacyclin in the irrigation fluid.[11] Third, we have confirmed that myocardium is a relatively poor producer of prostanoids in general and prostacyclin in particular, whereas the parietal pericardium and the epicardial surface are very active producers of prostacyclin in vitro. Furthermore, Ahumada et al[5] found that a pure cell line of rat myocytes grown in culture can produce only PGE_2 and $PGF_{2\alpha}$, whereas undifferentiated cardiac mesenchymal cells may produce, in addition, small amounts of 6-oxo-$PGF_{1\alpha}$. Therefore, it appears that prostacyclin in pericardial fluid is most likely derived from the serous membranes of the parietal pericardium and the epicardial surface. Mesothelial cells may be the primary cell source of this substance.[6]

Prostacyclin and regulation of coronary blood flow: In anesthetized dogs, prostacyclin is a potent coronary vasodilator when it is given intravascularly, and even when it is applied topically onto the epicardial surface.[8] The role of prostaglandins in regulation of coronary blood flow has been the subject of many investigations; the general conclusion has been that although prostaglandins are released into coronary venous blood during hypoxia and ischemia, they are neither essential nor contributory to the resulting increased blood flow.[1,2,21] One possible exception is the reactive hyperemia after prolonged periods (≥10 minutes) of coronary artery occlusion,[1,2] for this response is associated with release of PGE_2 and $PGF_{2\alpha}$ from the ischemic zone,[22] and both prostaglandin release and hyperemia are attenuated by pretreatment with indomethacin.[23,24]

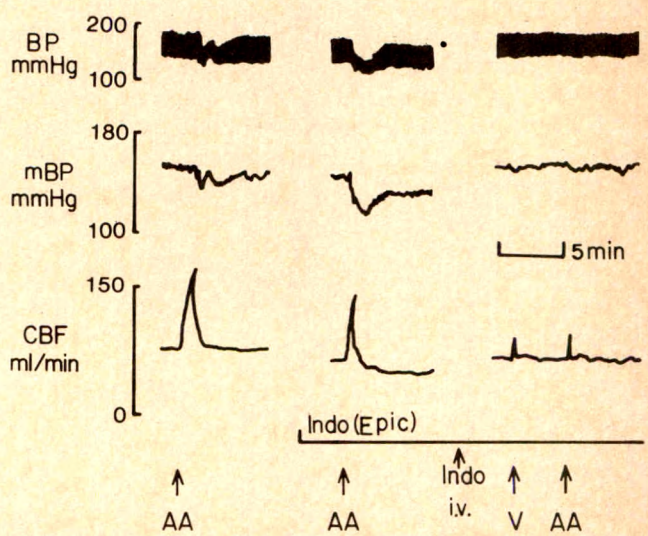

FIGURE 5. Effects of epicardial indomethacin (Indo) on a typical coronary blood flow (CBF) response to intraaortic injection of arachidonic acid (AA) (100 μg/kg). Indomethacin is given epicardially (Epic) (1 μg/ml) and intravenously (5 mg/kg) at the points indicated beneath the records. BP = blood pressure; mBP = mean BP; v = vehicle used for arachidonic acid.

Another role for cardiac prostanoids may be modulation of the coronary vasoconstrictor influence of activation of the renin-angiotensin system. Angiotensin II is known to stimulate prostacyclin release in most vascular beds,[20,25,26] including the lungs[27,28] and coronary circulation.[20] Furthermore, since angiotensin is a weak constrictor of the coronary circulation, it has been suggested that vascular prostacyclin attenuates the effects of the peptide.[20,25–29] Hintze and Kaley,[30] however, did not observe potentiation by indomethacin of the vasoconstrictor effect of angiotensin injected locally into the coronary artery of dogs. In contrast, Gunther and Cannon[31] reported marked enhancement by indomethacin of the coronary vasoconstrictor effect in the left ventricular wall, suggesting that systemic actions of the peptide were involved in stimulating release of a prostanoid modulator. We have shown that topical application of indomethacin onto the epicardial surface also increases the vasoconstrictor effect of angiotensin on coronary resistance vessels. We therefore suggest that prostacyclin of epicardial or pericardial origin modulates coronary vascular tone under these conditions.

Prostacyclin release into pericardial fluid was also stimulated by factors that increased afterload or heart rate. Increases of afterload that result in increased end-diastolic volume cause increased stretching of the epicardium and pericardium, and thereby increase friction between the pericardial surfaces. Such mechanical events may be the final common mechanism for increasing prostacyclin release, for manipulation of the heart in the pericardial sac also increased the release of prostacyclin.[11] Certainly, stretching of isolated blood vessels and cutting vessel rings increases the output of prostacyclin from these tissues.[32,33] Therefore, pericardial prostacyclin might also contribute to coronary vasodilation under other circumstances when afterload or heart rate is increased.

Pericardial prostacyclin does not, however, influence the coronary vascular response to all stimuli that increase its release. Experiments in isolated rabbit hearts indicate that prostanoids mediate the coronary vasodilator effects of bradykinin.[3,29] Intraaortic infusion of bradykinin also releases prostacyclin into the epicardial irrigation fluid, an effect partly related to the reflex tachycardia and partly to direct activation of phospholipase (Woodman DL, Dusting GJ, and Nolan RD, unpublished observations). Coronary vascular resistance was reduced by bradykinin, but this effect of the peptide was not sustained. Furthermore, although topical indomethacin (1 μg/ml) abolished bradykinin-induced release of prostacyclin, the coronary vascular response to bradykinin was not altered (Woodman et al, unpublished observations). Therefore, pericardial release of prostacyclin does not contribute to the coronary vasodilator action of bradykinin.

Possible roles of pericardial prostacyclin in myocardial ischemia: That bradykinin releases prostacyclin from the epicardial surface might have other consequences for myocardial ischemia. Bradykinin is generated in the ischemic myocardium and can be found in coronary sinus blood samples after coronary artery occlusion.[34] This peptide may have a local role in redistribution of coronary blood flow after infar tion,[29] but in addition, it stimulates sensory nerv endings in the ventricular wall.[35,36] Since bradykinin a potent pain-producing (algesic) substance, and i epicardial application also elicits sympathetic press reflexes accompanied by tachycardia, it has been su gested that bradykinin causes the pain and reflex even that accompany attacks of angina pectoris.[37] Furthe more, prostacyclin and PGE_2 are hyperalgesic,[38] an epicardial application of these prostanoids sensitize chemosensitive nerve endings and potentiates the refle increases in arterial pressure and heart rate induced b bradykinin.[9,10,37] Indomethacin has the opposite actio reducing pain and bradykinin-induced pressor reflex es.[37] Staszewska-Barczak and colleagues[9,10] propose that endogenous prostacyclin, released in the ischemi left ventricular epicardium after bradykinin generatio may act in concert with the peptide to signal angina Prostacyclin of pericardial origin may also sensitiz afferent nerves to the pain-producing effect of brady kinin in pericardial inflammation. The increased releas of prostacyclin into pericardial fluid may thus be factor in initiating the nociceptive response, as warning that an inappropriate stimulus to the hear should be withdrawn.

Others have suggested that prostacyclin may also b released from the ischemic myocardium itself and tha it may protect against early postinfarction arrhyth mias,[39,40] limit ischemic damage[41] and reduce infarc size.[42] Whether prostacyclin released into the pericar dial fluid may confer similar protective effects on th heart is not known. A mechanism that might contribut to protection of the ischemic myocardium involves fa cilitation of depressor chemoreflexes of vagal origin, a action which prostacyclin has been found to exert whe infused into the circulation.[9] Predominance of vaga reflexes reduces sympathetically mediated pressor re flexes and sympathetic drive to the heart, thereby re ducing the cardiac work load and oxygen demand. Pericardial prostacyclin, however, is unlikely to exer this type of action, because it does not influence vaga reflexes when applied epicardially. The functions o endogenous prostacyclin in the ischemic heart clearly require further study.

Pericardial prostacyclin and large coronary vessel tone: The suggestion that thromboxane A (TxA_2) may evoke coronary artery spasm in humans has attracted great interest. Platelet activation apparently occurs during vasotonic angina,[43] and elevated levels o TxB_2 (the hydration product of TxA_2) have been found in peripheral blood[44] and coronary sinus blood from patients with variant angina.[45] Prostacyclin is an endogenous physiologic antagonist of TxA_2, and coronary vasoconstriction might equally result from a deficiency of prostacyclin formation. The coronary vascular site of prostacyclin biosynthesis is obviously of considerable importance in this regard. However, the large coronary vessels in which vasospasm occurs are located in the epicardial surface, with only a serous membrane and adventitia separating the vascular smooth muscle from the pericardial space. The tone of these vessels may well be influenced by the very high concentrations of prostacyclin found in pericardial fluid. Aiken et al[46] showed

that topical application of prostacyclin over partially obstructed coronary vessels in dogs prevented platelet thrombi forming in these vessels at the sites of obstruction. Furthermore, it has recently been reported that indomethacin reduces coronary blood flow in patients with obstructions of the left coronary artery.[47]

Thus, pericardial fluid prostacyclin might represent an important mechanism for preventing constriction of the large coronary vessels, especially if platelet activation is a contributory factor to vasospasm. Moreover, if the coronary vessels are atheromatous, the capacity to stimulate pharmacologically the vascular synthesis of prostacyclin may be very much reduced,[13,48] whereas the pericardial site of synthesis is less likely to be impaired. Our studies indicate that therapeutic interventions might usefully take account of endogenous prostacyclin produced by the pericardium.

Acknowledgment: We are grateful to Wendy Davies and Tracey Drysdale for skillful technical assistance. We also thank J. R. Vane, DPhil, DSc, FRS, and J. E. Pike, DPhil, of The Wellcome Research Laboratories (Beckenham, Kent, United Kingdom) and The Upjohn Company (Kalamazoo, Michigan), respectively, for gifts of prostacyclin sodium. The antibody for TxB_2 was obtained as purified anti-TxB_2 rabbit IgG (a gift from J. Bryan, MD). Anti-PGE_2 antiserum was a gift from L. Levine, PhD; anti-$PGF_{2\alpha}$ antiserum was a gift from G. D. Thorburn, MD; anti-6-oxo-$PGF_{1\alpha}$ antiserum was a gift from L. C. Best, PhD. [^{3}H] arachidonic acid metabolites were obtained from New England Nuclear (Boston, Massachusetts) or the Radiochemical Centre (Amersham, United Kingdom).

Prostanoids and Cardiac Reflexes of Sympathetic and Vagal Origin

JANINA STASZEWSKA-BARCZAK, MD, PhD

Prostaglandins in concentrations too low to stimulate afferent nerve endings in the heart may sensitize them to chemical or mechanical stimuli that activate cardiac reflexes during myocardial ischemia. Bradykinin, which is released from the heart during ischemia, elicits sympathetically mediated reflex pressor effects and tachycardia when applied in low doses (0.1 to 1 μg) to the epicardium of the left ventricle in open-chest, anesthetized dogs. The reflex pressor effects evoked by bradykinin are reduced after inhibition of prostaglandins biosynthesis with indomethacin and potentiated by concomitant topical application of low doses (0.1 to 0.3 μg/min) of PGE_1 or PGE_2 and prostacyclin (PGI_2). The pressor and tachycardic responses to bradykinin are also enhanced after temporary (10-minute) coronary occlusion; this potentiation is abolished by indomethacin treatment and can be restored by superfusing the ventricle with prostaglandins. Nicotine is known to excite mechanosensitive vagal receptors with afferent C fibers, which supply the left ventricle, and to elicit reflex hypotension and bradycardia. This depressor vagal reflex evoked by epicardial or intracoronary administration of nicotine (10 to 50 μg) was not affected by either indomethacin or by topical application of PGE_1, PGE_2, or PGI_2. Also, intracoronary infusion of PGE_2 (0.1 to 0.3 μg/min), which enhanced the pressor reflex effects of bradykinin, was without effect on nicotine-induced depressor reflex. However, intracoronary infusion of PGI_2 (0.1 to 0.3 μg/min) significantly enhanced the hypotensive and bradycardic responses to nicotine and, at the same time, reduced sympathetically mediated reflex effects of bradykinin. The hypotensive effects induced by epicardial or intracoronary administration of nicotine were also significantly enhanced during intravenous infusion of subdepressor doses of PGI_2 (5 to 20 ng/kg/min). Treatment with captopril, which enhances the endogenous production of prostaglandins, greatly enhanced the reflex depressor effects of nicotine; this potentiating effect of captopril was completely abolished by indomethacin treatment. An increase in the magnitude of nicotine-induced reflex depressor effects was also observed after intravenous injection (1 μg/kg) or infusion (25 to 50 ng/kg/min) of prostaglandin D_2. A working hypothesis is proposed to account for the role of prostanoids in activation of cardiac reflexes during myocardial ischemia.

Cardiac reflexes, together with reflexes arising from the respiratory system and arterial baro- and chemoreceptors, play an important role in the regulation of volume and pressure.[1] Cardiac reflexes are also considered an important factor in human pathophysiology, particularly in conditions such as coronary heart disease,[2–5] congestive heart failure[6] or hemorrhage.[7]

Cardiac reflexes originate from a variety of sensory receptors present in all 4 cardiac chambers and the coronary arteries. The receptors are connected to myelinated and unmyelinated afferent fibers that run centrally by way of 2 separate pathways, 1 with the vagus nerves to the medulla and 1 with the cardiac sympathetic nerves to the upper thoracic segments of the spinal cord.[8] There are many important differences in anatomic distribution, functional characteristics, and reflex properties of cardiac receptors associated with the 2 afferent systems innervating the heart; these were reviewed in detail by Coleridge and co-workers.[9–11] Briefly, receptors associated with afferent fibers in cardiac sympathetic nerves and cell bodies in the dorsal root ganglia provide a widespread, continuous sensory innervation of the surface of the heart that extends to the roots of the great vessels and the parietal pericardium. This widespread and diffuse distribution of the sympathetic afferent innervation contrasts with the

more restricted distribution of the vagal afferent system, which is generally more selective.

Receptors connected to myelinated vagal afferent fibers innervate mainly the low-pressure chambers and are confined predominantly to the atriovenous junctions.[12] The ventricles receive relatively few myelinated but many unmyelinated afferent fibers from the vagus. The endings with the afferent C fibers are particularly numerous in the left ventricle and are situated in the epicardium and at all depths of the ventricular epicardium.[9,10] Nerve endings with myelinated vagal afferents are mechanoreceptors. Those located in the myocardium of both ventricles and around the left coronary artery discharge during ventricular systole and this increases with increasing ventricular pressure.[12] Ventricular endings with unmyelinated afferents, on the other hand, have a sparse and irregular discharge at normal cardiovascular pressures. Many of these endings are mechanosensitive and respond with increased firing, usually in systole, to increases in end-diastolic pressure, ventricular wall tension, and during vigorous beating produced by epinephrine.[13,14] These mechanosensitive vagal receptors with C-fiber afferents are also susceptible to chemical stimulation. They are activated by intracoronary or epicardial application of nicotine and veratroidine and elicit reflex decreases in the heart rate and arterial pressure.[15] There is another group of vagal unmyelinated afferent endings which are little sensitive to mechanical stimulation produced by changes in cardiac volume or pressure, but are excited by foreign chemicals, such as phenyl diguanide and capsaicin,[9,10] and by endogenous substances, such as bradykinin[16] and prostaglandins.[17,18] For this group of afferent receptors, the term "chemosensitive endings" has been proposed by Coleridge and Coleridge[10,11] to distinguish them from the conventional chemoreceptors, since they are not stimulated by hypoxia or cyanide.

Myelinated and unmyelinated afferent fibers traveling in the cardiac sympathetic nerves and supplying the terminals in the walls of the ventricles and the coronary arteries on the surface of the heart are often silent or have a sparse discharge, comparable to that of vagal mechanoreceptors with C-fiber afferents.[8,9,11] Many of these endings are mechanosensitive and are activated by light stroking and during increases in transmural pressure.[9,19] However, the frequency of discharge evoked by even a large increase in transmural pressure is usually low and poorly sustained[19] compared with the high frequency of discharge in vagal mechanoreceptor afferents, which is well maintained for the duration of the stimulus.[9,12] The brief and relatively modest response of sympathetic afferent endings to increases in ventricular volume or pressure is in marked contrast to the high frequency of firing, lasting for several minutes, that occurs in response to stimulation evoked by endogenous chemical substances such as lactic acid, bradykinin and potassium.[9,20–23]

Cardiac reflexes arising from stimulation of vagal and sympathetic afferent endings in the ventricle are opposite in sign. Reflexes mediated by the medullary vagal input are generally inhibitory or depressor and analodiated by afferent sympathetic fibers or by the spinal input are in contrast mainly excitatory or pressor.[8,10,24–29] How the 2 afferent cardiac systems, medullary and spinal, are connected and interact at the central level is unclear.[1,30] However, several types of interaction between the 2 systems are known to operate. Vagal afferent activity arising from the heart exerts tonic inhibition on sympathetic efferent activity, particularly to the heart and kidney; this is most apparent when tonic inhibitory influences arising from the arterial baroreceptors have been minimized.[14] Activation of various vagal afferent endings that supply the ventricles by mechanical or chemical stimulation causes reductions in the heart rate and blood pressure that result from a reflexly mediated increase in vagal efferent discharge to the heart and inhibition of sympathetic efferent activity in cardiac[31] and peripheral constrictor nerves, including those to the kidney, muscle and intestinal beds.[14] Stimulation of cardiac sympathetic afferent fibers is, on the other hand, associated with reflex inhibition of cardiac vagal efferent activity and an increase in sympathetic efferent discharge to the heart.[31] There is also evidence for the existence of a cardiocardiac vagosympathetic negative feedback mechanism activated by sympathetically mediated increases in ventricular contractility.[32,33]

It is not clear whether sympathetic afferent activity arising from the heart participates in normal cardiovascular control. Unlike vagal mechanoreceptors, the endings of both myelinated and unmyelinated sympathetic afferent fibers appear to be poorly designed to provide precise continuing information about changes in mechanical performance of the cardiac pump.[11,19] However, their high sensitivity to touch, and particularly to stimulation by endogenous chemical agents, makes them well suited to signal sudden changes in cardiac metabolism and alterations in physicochemical external environment of the heart.[9,11]

Prostanoids and Cardiac Reflexes of Sympathetic Origin

Early research on the actions of prostaglandins revealed that although high doses may cause overt pain in man[34] or a pain-like response in experimental animals,[35] a typical effect of low concentrations that occur in inflammation or other forms of tissue injury such as ischemia is induction of hyperalgesia, that is, a state in which pain can be elicited by low-intensity mechanical or chemical stimulation.[34] The hyperalgesic effect, which seems to be peculiar to prostaglandins of the E type and PGI_2,[36] is attributed to their ability to sensitize sensory nerves by triggering a metabolic process that involves activation of adenyl cyclase, elevation of adenosine 3′:5′-cyclic phosphate (cyclic AMP) and calcium concentration at the nerve terminal with a subsequent decrease in the excitation threshold.[37]

Afferent fibers in the cardiac sympathetic nerves appear to be soley responsible for signaling the pain of myocardial ischemia, because the pain of angina in man and the pain-like pseudaffective response to acute coronary occlusion in conscious dogs are relieved by

thoracic ganglia, but not by vagotomy.[38,39] Sympathetic afferent endings in the heart not only signal pain, but also initiate excitatory cardiovascular reflexes, manifested by increases in arterial pressure, heart rate, ventricular contractility and myocardial excitability.[3,25,28,29,40] Hypertension and tachycardia frequently occur at the onset of anginal attacks[2,41] and myocardial infarction,[5] and there is good evidence to suggest that these excitatory reflexes can contribute to the development of arrhythmias and may even lead to ventricular fibrillation.[42]

The precise mechanism of stimulation of the sympathetic afferent nerves by myocardial ischemia is not known. Experimental studies suggested that endings associated with myelinated afferent fibers are excited mainly mechanically, by stretching and shortening of the bulging ischemic wall, whereas endings with unmyelinated afferents are stimulated mainly by chemical agents released locally during ischemia.[25,43,44]

Chemical changes associated with ischemia include accumulation of lactic acid, release of adenosine and potassium, and enhanced formation and release of bradykinin and prostaglandins.[45–51] Many of these substances, particularly bradykinin, are potent algesic agents.[52] Bradykinin applied to the surface of the left ventricle or injected into the coronary artery stimulates afferent sympathetic terminals with both A and C fibers,[21,22] and in lightly anesthetized animals, this increase in afferent activity is often accompanied by a pseudaffective response.[21,52] In anesthetized dogs[28,29] or cats,[22,53] minute doses of bradykinin (1 ng to 1 μg) applied directly to the epicardium of the left ventricle elicit dose-dependent, sympathetically mediated increases in blood pressure and heart rate. These observations, together with those of increased output of bradykinin after coronary ligation in dogs,[48] suggest that this chemical substance may have a major role in activation of sympathetic afferent nerves during ischemia. However, Uchida and Murao[20] found that treatment with trasylol, which inhibits bradykinin formation,[54,55] resulted in only slight (up to 20%) inhibition of the ischemia-induced excitation of both A and C sympathetic afferent nerves. On the other hand, pretreatment with sodium bicarbonate, to prevent acidosis, completely suppressed excitation of the unmyelinated fibers induced by coronary occlusion. Also, aspirin treatment was found to be effective in reducing ischemia-induced excitation of afferent C fiber by as much as 72%, and that of myelinated A fibers by 38%.

In another study, Uchida and Murao[21] demonstrated that stimulation of A and C sympathetic afferent fibers evoked by epicardial application of bradykinin was also significantly reduced by aspirin; they attributed this effect to the competitive occupation of chemosensitive sites at the pain receptors, as originally suggested by Guzman et al.[52] However, the discovery that aspirin-like drugs inhibit the biosynthesis of prostaglandins,[56] together with findings that prostaglandins induce hyperalgesia by sensitizing sensory nerves to mechanical and chemical stimulation[34] led to the proposal that the analgesic activity of anti-inflammatory agents such a aspirin and indomethacin is due to the removal c prostaglandin release and, hence, their sensitizing actio on sensory nerves.[34]

In agreement with the results of the action potentia studies,[21] Staszewska-Barczak et al[28] found that refle increases in blood pressure and heart rate induced b topical application of bradykinin to the left ventricle i dogs are significantly attenuated by treatment wit indomethacin. Furthermore, it was found that treat ment of the heart surface with minute amounts of PGE or PGE_2 (10 ng/min) restored reflex pressor response to bradykinin which had been reduced by indometha cin; $PGF_{2\alpha}$, in doses up to 1 μg/min, had no effect. Wit higher doses of PGE_1 (0.1 to 1 μg/min), the pressor ef fects produced by threshold doses of bradykinin (20 t 30 ng) were nearly doubled; even the reflex pressor re sponse to a maximal dose of bradykinin (1 μg) was po tentiated by almost 50%. This potentiation was stil evident at 30, and sometimes 60 minutes after prosta glandin treatment. In some experiments, the sensitivity to bradykinin was increased so much that the refle pressor effects could be evoked by doses as low as 1 ng It is noteworthy that PGE_1 and PGE_2 in doses up to 1 μg were without pressor effects by themselves.[28] Later Baker et al[57] recorded action potentials in cardiac sympathetic afferent fibers in cats and confirmed that epicardial application of PGE_1 in doses (0.1 μg) that alone did not excite nerve endings in the ventricle potentiated the stimulating effect of bradykinin on these endings.

The release of prostaglandins from the heart in response to ischemia, hypoxia or mechanical stimulation has been observed in the isolated heart preparation[5] and in intact animals with an open[49] and closed chest.[5] Recently, cardiac prostaglandin release was also demonstrated during myocardial ischemia induced by atrial pacing in patients with coronary artery disease.[51] Acute coronary occlusion in the closed-chest dog was associated with an enhanced release of PGE_2 and $PGF_{2\alpha}$. $PGF_{2\alpha}$ was found to originate only from the ischemic zone, whereas PGE_2 was released from the ischemic as well as the nonischemic myocardium.[50] As PGE_2 and $PGF_{2\alpha}$ are synthesized mainly by the cardiac myocytes,[59] it is possible that abnormal stretching and shortening of the ischemic zone, as well as a compensatory increase in contractions of the nonischemic myocardium, were mainly responsible for stimulating an increased synthesis and release of these prostaglandins. In our experiments,[28] pronounced increases in the magnitude of reflex pressor and tachycardic responses to epicardial bradykinin were observed after temporary (10-minute) coronary occlusion. The degree of potentiation resulting from regional myocardial ischemia was comparable with that produced by application of higher doses of PGE_1 (1 μg/min). The potentiating effect of ischemia could be abolished by pretreatment with indomethacin and then restored by superfusing the ischemic area with PGE_1 or PGE_2. These results, together with observations that postocclusion augmentation of impulse activity in sympathetic

ished by aspirin,[20] clearly indicated that locally released prostaglandins were mainly responsible for ischemia-induced potentiation of the afferent nervous activity and the reflex effects of bradykinin.

PGI_2 is the product of the conversion of prostaglandin endoperoxides by a microsomal enzyme, PGI_2 synthetase, which is most highly concentrated in the vascular endothelial cells. All vascular tissues, including coronary vasculature, from all species so far tested were found to generate and release PGI_2 predominantly.[60,61] However, other tissues, such as pericardium and peritoneum, which are covered by a layer of the squamous epithelial cells (the so-called mesothelium), can also generate high amounts of PGI_2.[62] PGI_2 presumably formed by the epicardial mesothelium is also released during superfusion of the dog's heart in situ with Krebs' solution and the output of PGI_2 into the perfusate is markedly enhanced by mechanical stimulation of the surface of the heart, as well as by increases in cardiac work induced by aortic constriction, bilateral carotid occlusion, or intravenous administration of pressor doses of angiotensin.[63]

Recently, Ferreira et al[36] found that PGI_2, like PGE_2, can induce hyperalgesia. They also showed that the hyperalgesic effect of PGI_2 is quick in onset but short-lasting, whereas hyperalgesia caused by PGE_2 develops more slowly but is prolonged. Our studies[64–66] have shown that PGI_2 significantly potentiated the reflex pressor effects of bradykinin when applied in low doses (0.1 to 0.3 μg/min) directly to the surface of the left ventricle in dogs, but not when infused in equal doses into the coronary artery. In this respect, the action of PGI_2 differed from that of PGE_2, which was equally effective in enhancing the reflex effects of bradykinin, whether applied topically or infused into the coronary blood supply to the left ventricle. Also, the duration of the potentiating effect, unlike that of PGE_2, was extremely brief and disappeared as soon as application of PGI_2 was discontinued. These observations led us to propose that PGI_2 released by the epicardial or pericardial mesothelium or both may contribute to the signaling of pain and excitatory cardiovascular reflexes when kinin formation occurs during myocardial ischemia or pericardial inflammation.[66]

Prostanoids and Cardiac Reflexes of Vagal Origin

Recently, Hintze,[67] Chapple,[68] and their co-workers found that the hypotension induced by intravenous, intracoronary, or left atrial injections of high doses of PGI_2 (10 to 30 mg) in dogs is frequently accompanied by bradycardia. In contrast, the hypotension induced with equal or higher doses of PGE_2 is always closely followed by tachycardia, presumably through a baroreflex mechanism. Observations that bradycardia induced by PGI_2 was reduced or abolished by atropine suggested that a reflexly mediated increase in vagal efferent discharge to the heart, rather than a direct effect of PGI_2 on cardiac pacemaker cells, was responsible for the bradycardic effect. Because bilateral vagotomy not only reversed the bradycardia, but also reduced the hypotensive response, these investigators[67,68] proposed that the afferent pathway of the reflex was also in the vagus and that at least part of the hypotensive actio of PGI_2 is also reflexly mediated.

Subsequent action potential studies showed that hig doses of PGI_2 (1 to 20 μg) injected into the left atriu in dogs stimulated vagal afferent C fibers with chemo sensitive endings in the ventricle.[18] High doses of PGE (1 to 5 μg/kg) and bradykinin (0.3 to 1 μg/kg) injecte into the left atrium also stimulated chemosensitiv vagal afferent endings in the atriums, ventricles an adjacent great veins and arteries.[16,17] The stimulator effect appeared to be specific for chemosensitive vaga endings, since neither afferent C fibers of mechano sensitive ventricular endings nor afferent A fibers wer excited by PGI_2, PGE_2 or bradykinin. It was therefor postulated that stimulation of these chemosensitiv vagal afferent endings in the ventricle initiate refle bradycardia and hypotension produced by intracoro nary administration of prostaglandins and bradyki nin.[11,16–18] However, reflex hypotension and brady cardia after intracoronary injection of bradykinin wer observed only in dogs under barbiturate anesthe sia,[69,70] which depresses sympathetic nervous activity.[7] In dogs lightly[52] or fully anesthetized with chlo ralose,[28,72] intracoronary injection of bradykinin ma cause either pressor, depressor or biphasic changes i blood pressure that are always accompanied by tachy cardia. Hypotension associated with tachycardia is als produced by intracoronary or intravenous administra tion of PGE_2.[67,68]

A phenomenon of "sensitization," that is, an enhanced responsiveness on repeated stimulation, has been attributed to a decrease in the excitation threshold of polymodal sensory receptors associated with afferent C fibers.[73] Although the original concept was based on studies with polymodal (the term indicating that the receptors are excited by both mechanical and chemical stimuli) cutaneous nociceptors,[73,74] the phenomenon of sensitization, which involves a chemical intermediary,[73] may also apply to polymodal sensory nerve endings in the heart. Lombardi et al[75] drew attention to the ability of bradykinin to stimulate mechanosensitive sympathetic afferent endings in the heart, as well as a vast population of somatic C fiber afferent receptors in the skin and skeletal muscles, which are all polymodal. On the other hand, the stimulatory action of bradykinin on sensory nerves is associated with its ability to enhance prostaglandin production.[76,77]

Of the 3 types of vagal sensory receptors in the heart, only mechanosensitive endings with C afferent fibers, which innervate predominantly the left ventricle, may be regarded as polymodal since they are equally susceptible to mechanical stimulation by changes in ventricular volume and pressure or contractility, and to chemical stimulation with substances like nicotine.[13] These vagal afferent endings are also activated after acute coronary occlusion, probably as a result of increased end-diastolic ventricular pressure,[78] and are thought to be responsible for the reflex vasodilatation associated with myocardial ischemia.[79]

Sleight[15] observed a decrease in arterial pressure and bradycardia after intrapericardial or intracoronary injection of 50 to 100 μg of nicotine in dogs. Similar re-

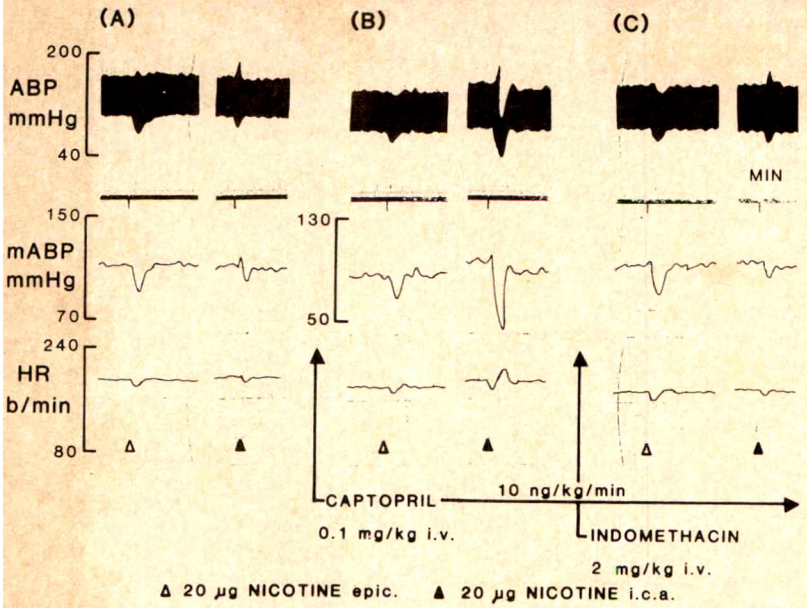

FIGURE 1. Pulsatile blood pressure (ABP), mean arterial pressure (mABP) and heart rate (HR) from an anesthetized, open-chest dog. Reflex hypotensive effects and bradycardia are induced with 20 μg of nicotine applied either to the surface of the left ventricle (**open triangles**) or injected into the left anterior coronary artery (**closed triangles**) under control conditions (**A**) and during treatment with captopril alone (**B**) and after intravenous administration of indomethacin (**C**). Treatment with captopril greatly enhanced the hypotensive response to intracoronary injection of nicotine, and this potentiating effect was completely abolished after indomethacin. Time scale is in minutes.

sponses occurred in our experiments in dogs with epicardial or intracoronary administration of 10 to 50 μg of nicotine. Our early investigations have shown that in contrast to the sympathetic pressor reflex evoked by epicardial application of bradykinin, the depressor vagal reflex induced by epicardial application of nicotine was not affected by treatment with indomethacin or by topical application of PGE_1 and PGE_2.[28] In subsequent studies,[64–66] topical application of PGI_2 (0.1 to 0.3 μg/min) and intracoronary infusion of PGE_2 (0.1 to 0.3 μg/min) also failed to influence the depressor and bradycardic responses induced by nicotine. However, a significant increase in the magnitude of the nicotine-induced reflex hypotension and bradycardia occurred during intracoronary or intravenous infusion of subdepressor doses (0.1 to 0.3 μg/min and 5 to 20 ng/kg/min, respectively) of PGI_2. Moreover, in several dogs that initially failed to respond to nicotine with reflex hypotension and bradycardia, these responses could be elicited during intravenous infusion of PGI_2.

It was still unclear, however, why the reflex effects of nicotine, unlike those of bradykinin, were not affected

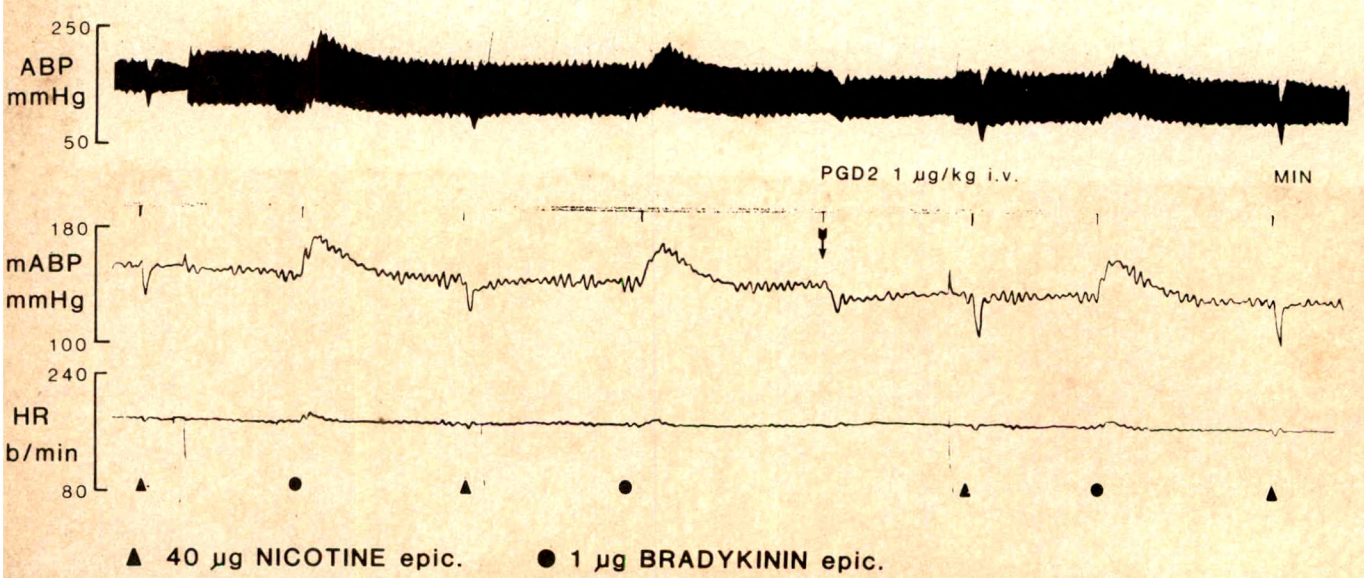

FIGURE 2. Potentiation of reflex depressor effects of nicotine after intravenous injection of prostaglandin D_2 (PGD_2). Records of pulsatile (ABP) and mean arterial pressure (mABP) and heart rate (HR) from a dog show responses produced by topical application to the left ventricle of 40 μg of nicotine (**triangles**) and 1 μg of bradykinin (**circles**) before and after intravenous injection of 1 μg/kg of PGD_2 (**arrow**). Injection of PGD_2 produced a decrease in blood pressure that was closely followed by a small increase in heart rate. After PGD_2, the magnitude of pressor and tachycardic response to bradykinin was not changed, but the hypotensive and bradycardic effects evoked by epicardial application of nicotine almost doubled. Time scale is in minutes.

by indomethacin. Some insight into this question was provided by the results of our recent investigations with captopril.[72] Captopril is an inhibitor of carboxy-dipeptidase, which functions as the angiotensin-converting enzyme and also as the major bradykinin-inactivating enzyme kininase II.[80] Consequently, treatment with captopril inhibits the formation of angiotensin II and at the same time enhances plasma level of kinins and potentiates vasodilator and other pharmacologic effects of exogenous bradykinin.[55,76] Bradykinin activates phospholipase A_2 and thus increases the availability of arachidonic acid for generation of various prostanoids,[81] which in turn contribute to vasodilator and other effects of bradykinin.[76] Observations that a decrease in blood pressure produced by captopril was reduced after indomethacin treatment suggested that the hypotensive effect was, at least in part, due to an increased release of prostaglandins.[82] Clough et al[83] reported that a decrease in blood pressure produced by captopril is not accompanied by a baroreflex-mediated increase in heart rate.[83] Our investigations with captopril[72] indicated that an enhanced reflex activity of vagal afferent receptors in the left ventricle, mediated by a prostaglandin mechanism, may contribute to the lack of effect on heart rate observed with captopril. Treatment with captopril greatly enhanced the magnitude of reflex depressor effects evoked by intracoronary administration of nicotine, and this potentiation was completely abolished by indomethacin (Fig. 1). These results clearly indicated that endogenous prostaglandins can sensitize polymodal vagal afferent endings in the ventricle and thereby enhance reflex depressor effects resulting from chemical or mechanical stimulation of these receptors. The sensitizing effect was probably due to an enhanced release of PGI_2 into the coronary or systemic circulation, since potentiation was particularly pronounced with intracoronary rather than with epicardial application of nicotine, and since PGI_2, but not PGE_2, potentiated the reflex effects of nicotine when infused in low doses into the coronary artery or intravenously.[64,65]

Recently, Hemker and Aiken[84] observed that the hypotension produced by intraarterial or intravenous injections of PGD_2 in cats was accompanied by bradycardia rather than tachycardia. Since bradycardia was blocked by treatment with atropine, it was suggested that PGD_2 activated vagal pathways. Our preliminary investigations with PGD_2 have shown that in anesthetized dogs, intravenous injections of 1 μg/kg of PGD_2 usually produce a small hypotensive effect associated with an increase in heart rate. However, in 4 of 6 dogs, we found a marked potentiation of the reflex hypotensive and bradycardic responses to epicardial or intracoronary nicotine, after intravenous injection of 1 μg/kg of PGD_2. A tracing from an experiment illustrating this effect is shown in Figure 2. The potentiating effect was usually prolonged, lasting for up to 30 minutes. In some experiments, further increases in the magnitude of nicotine-induced responses could be produced by an intravenous infusion of PGD_2 at a rate of 25 to 50 ng/kg/min. Surprisingly, no consistent potentiation could be obtained with intracoronary injections (0.3 to 1 μg/kg) or infusions (0.3 to 1 μg/min) of PGD_2, even though injections frequently evoked a decrease in blood pressure associated with bradycardia.

Recent investigations indicate that PGD_2 is formed in the blood and, like PGI_2,[85] is not inactivated during the passage through the lung; hence, it functions as a circulating hormone.[86] Our observations that intravenous PGD_2 enhances reflex effects of nicotine suggest that blood-borne PGD_2 may contribute to activation of vagal cardiac reflexes. However, the mechanism of the potentiating action of PGD_2 requires further investigation.

Role of Prostanoids in Regulation of Cardiac Reflex Activity and Coronary Resistance During Myocardial Ischemia: A Working Hypothesis

In 1976, Needleman[87] proposed a working hypothesis to account for the role of bradykinin and prostaglandins in modulating coronary resistance and cardiac reflexes associated with regional myocardial ischemia. According to this hypothesis, bradykinin released in the heart in response to ischemia promotes synthesis of PGE_2, and these 2 substances, acting independently or together, produce coronary dilatation and initiate cardiac chemoreflexes. As a result, coronary dilatation increases the oxygen supply, whereas reflex bradycardia decreases oxygen demand, thereby reducing the ischemia. In addition, the initiation of the pain sensation serves as the signal of an inappropriate stimulus to the heart that must be withdrawn.

It is now well established that coronary arteries are dilated by PGI_2 and contracted by PGE_2.[61,88] Furthermore, PGI_2, but not PGE_2, can induce[67,68] or potentiate[64,65] cardiac reflexes of vagal origin when administered into the coronary or systemic circulation. PGI_2 and not PGE_2 is a predominant active metabolite or arachidonic acid in blood vessels, including coronary vasculature.[61,89,90] Arachidonic acid is transformed into PGI_2 on passage through the lungs in vivo, whereas PGE_2 cannot be detected in arterial blood during infusion of the precursor fatty acid.[91] Furthermore, PGI_2 is only partially inactivated in 1 complete passage around the circulation,[85] a finding that reinforces the concept[92] that PGI_2 can function as a circulating hormone. However, Gryglewski[93] reported that there is a strong reduction in PGI_2 formation by hearts or vessels of rabbits made atherosclerotic. Similarly, there have been reports that human atherosclerotic tissue does not produce PGI_2, whereas tissue obtained from a nearby normal vessel does.[94] Patients with ischemic heart disease also have significantly lower levels of PGI_2 in the circulation, as well as lower capacities to generate and release PGI_2 in response to various stimuli (including ischemia) compared with healthy subjects who are the same age.[95] On the basis of these and other findings, Gryglewski[93] advanced a hypothesis that atherosclerosis is a disease from a deficiency of PGI_2 due to inhibition of PGI_2 synthetase by lipid peroxides or corresponding free radicals generated during hyperlipidemia.

PGI_2 is not only a vasodilator substance, but also a potent inhibitor of platelet aggregation in vitro and in vivo.[61,96–98] Aiken et al[98] showed that intravenous infusion of low doses of PGI_2 can prevent or reverse

thrombus formation in partially obstructed coronary arteries in dogs. On the basis of these and other observations, Moncada and Vane[61,96,97] suggested that PGI_2 or its chemical analogs could be used as a "hormone replacement" therapy in conditions in which excessive platelet aggregation is involved, such as acute myocardial infarction or crescendo angina.

Recently, therapeutic potential of PGI_2 was evaluated in patients with proved coronary artery disease. Bergman et al[99] reported that intravenous infusion of PGI_2 at rates of 2 to 8 ng/kg/min significantly reduced coronary vascular resistance and platelet aggregation induced with adenosine diphosphate. These effects on platelets and coronary resistance were accompanied by a prolongation of mean atrial pacing time to produce angina. Of particular interest, however, were observations reported by Szczeklik et al.[100] They found that low doses of PGI_2 (5 or 10 ng/kg/min) infused intravenously for 72 hours to patients with an ischemic heart disease completely abolished or significantly reduced a recurrence of attacks of spontaneous angina. However, anginal attacks precipitated by atrial pacing were not influenced by PGI_2 treatment. Since reductions in coronary vascular resistance and platelet aggregability were unlikely to be different in patients with spontaneous and pacing-induced angina (these were not measured), other actions of PGI_2, such as its ability to potentiate the effects of vagal stimulation in the heart, should be considered. Our experiments showed t small increments of PGI_2 in the circulation not c enhanced reflex effects of vagal origin, but also redu sympathetically mediated pressor responses evo with bradykinin.[64,65] There is also evidence for the istence of a cardiocardiac, vagosympathetic nega feedback reflex which can be initiated by sympath cally mediated increases in ventricular contractility. Increases in blood pressure and heart rate, which be attributed to reflex activation of sympathetic car and peripheral nervous activity,[3,25,28] frequently p cede the onset of pain in spontaneous angina.[2,41]

The effects of sympathetic stimulation may counteracted by activation of a vagosympath negative feedback mechanism, which can, in turn, amplified by sensitizing action of PGI_2 on mecha sensitive afferent nerve endings in the heart. T mechanism is unlikely to have a role in buffering effects of direct sympathetic stimulation imposed pacing. This may explain the effectiveness of PGI suppressing the attacks of spontaneous, but not p ing-induced, angina that Szczeklik et al observed.[1]

A working hypothesis that evolved from recent perimental and clinical findings is presented in Fig 3. It is postulated that a sudden oxygen deficit, prec itated either by an increased work load or a local va spasm superimposed on coronary atherosclerosis, result in regional myocardial ischemia. Once ischer

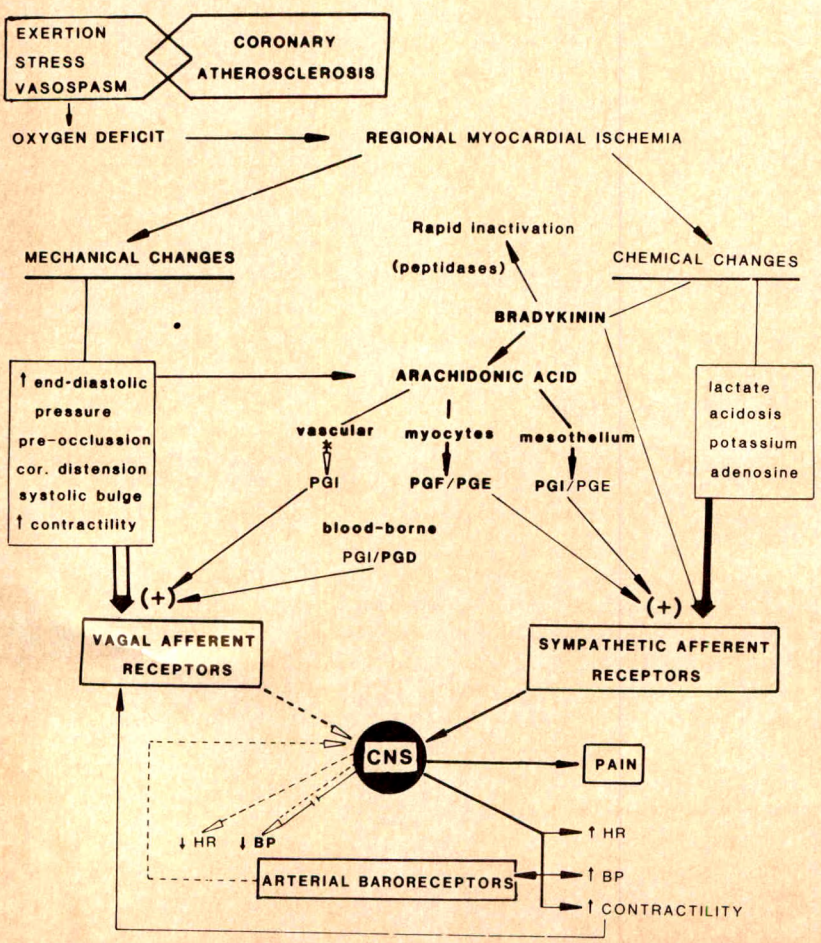

FIGURE 3. The events initiated by acute regional m cardial ischemia and their relative contribution to a vation of inhibitory and excitatory cardiovascular reflex BP = blood pressure; CNS = central nervous system; = heart rate.

occurs, mechanical and chemical changes are set in motion. A shift from aerobic to anaerobic metabolism leads to accumulation of lactic acid and local acidosis, which in turn can promote the release of potassium and adenosine and also activate kallikrein to form bradykinin. Concurrently, mechanical changes in left ventricular function and compliance with a subsequent increase in the end-diastolic ventricular pressure develop. These mechanical events, and particularly stretching and shortening of the bulging ischemic myocardium, can stimulate the release of arachidonic acid and increase generation of PGE_2 and $PGF_{2\alpha}$ by cardiac myocytes. Systolic bulging may also mechanically stimulate the pericardium to release PGI_2 and PGE_2 into pericardial fluid. On the other hand, distention of the coronary artery above the occlusion can stimulate PGI_2 synthesis by the residual healthy vascular endothelium. The synthesis of prostaglandins by various cell constituents of the heart and the pericardium can be further amplified by the release of arachidonic acid by bradykinin.

Except for the chemosensitive endings, activation of vagal afferent receptors in the ventricle can be attributed to mechanical stimulation. Activation of sympathetic afferent endings, on the other hand, may result predominantly from direct excitation by endogenous chemical substances acting in concert. Contribution of bradykinin to direct excitation may be restricted by its rapid inactivation by peptidases. However, by enhancing prostaglandin production, bradykinin can indirectly influence the sensitivity of vagal afferent endings to mechanical stimulation, and of sympathetic receptors to chemical stimulation by less potent but more stable substances such as lactate and potassium ions.

PGE_2 released from cardiac myocytes, together with PGI_2 deriving from epicardial and pericardial mesothelium, can sensitize sympathetic afferent receptors and thereby contribute to signaling of pain and to sympathetically mediated increases in blood pressure and cardiac rate and contractility. PGI_2 released into the coronary or systemic circulation could stimulate chemosensitive and sensitize mechanosensitive vagal receptors with C-fiber endings and, hence, contribute to reflex reductions in arterial pressure and heart rate. However, since PGI_2 synthesis by vascular endothelium is greatly reduced during atherosclerosis, this mechanism is unlikely to operate during ischemic heart disease unless this defect is corrected by administration of exogenous PGI_2. In the absence of PGI_2, blood-borne PGD_2 might contribute to activation of vagal afferent input from the heart. Of more importance in buffering the reflex effects of sympathetic stimulation may be activation of a negative feedback system through potentiation of cardiac vagal afferent activity by sympathetically mediated increases in ventricular contractility on the one hand, and activation of an inhibitory input from arterial baroreceptors on the other.

How the 2 inhibitory medullary inputs and the excitatory spinal input are connected and interact at the central level is not clear. On the output side, however, an amplified cardiac vagal efferent activity would tend to reduce cardiac rate and contractility, whereas reflex inhibition of sympathetic vasoconstrictor activity, together with stimulation of cholinergic sympathetic activity, would tend to reduce peripheral resistance and, consequently, blood pressure. These reflexly mediated mechanisms would reduce cardiac work and hence oxygen demand by the heart. Concurrently with reflexly mediated events, vasodilator metabolites such as adenosine[47] and, possibly, bradykinin,[87] would act to increase the oxygen supply. PGI_2 released from the residual healthy coronary endothelium or mesenchymal cells or both may contribute to coronary dilatation and at the same time reduce or reverse thrombus formation, increasing the patency of the vessel supplying blood to the ischemic area. All of the reflexly mediated and local mechanisms acting in concert may be responsible for the termination of an anginal attack uncomplicated by severe rhythm disturbances or circulatory collapse.

The present hypothesis incorporates in 1 framework a number of relevant, but hitherto unrelated, data on reflex and local changes occurring during regional ischemia resulting from obstruction of blood flow in the left anterior coronary artery. Acute ischemia of the posterior wall may trigger different reflex mechanisms[5] that were not considered in the present hypothesis.

Acknowledgment: I thank Dr. John R. Vane, who introduced me to the field of prostaglandin research, and Professor M. J. Rand who, although not personally involved in the field of prostaglandin or cardiac reflex research, was of great help and support in encouraging the work presented in this report. I also thank my students and friends, Denise E. Luk and Peter N. Nolan, for their invaluable help in carrying out the research project as well as preparation of the manuscript. Finally, I acknowledge the great kindness and patience of Elaine Sonerson in typing the manuscript. Special thanks are due to Dr. John E. Pike from the Upjohn Company, Kalamazoo, Michigan, for a generous supply of prostaglandins.

Variable Susceptibility to Dynamic Coronary Obstruction: An Elusive Link Between Coronary Atherosclerosis and Angina Pectoris

ATTILIO MASERI, MD, SERGIO CHIERCHIA, MD, GRAHAM J. DAVIES, MB, MRCP, and KIM M. FOX, MB, MRCP

Growing evidence suggests that dynamic coronary obstructions play an important but elusive role in the genesis of ischemic events. Dynamic coronary obstructions can develop during certain phases of coronary disease as a result of a variable combination of vasoconstriction, arterial wall lesions, and increased thrombotic tendency. In a certain phase of their disease some patients develop dynamic coronary obstruction, while others with a similar degree of fixed atherosclerotic obstruction do not.

Myocardial infarction and sudden death are much more likely to occur in angina pectoris of recent onset and during the waxing of symptoms than in the stable phases. If patients are to be managed rationally, it is important to know whether the onset and spontaneous variability of angina is caused predominantly by the progression of atherosclerotic coronary obstructions or by dynamic events that only transiently interfere with regional myocardial oxygen supply.

The investigators who specifically addressed themselves to this question favor the second hypothesis for most patients. Angiographic studies show that the severity of coronary atherosclerotic lesions is similar in stable and unstable angina.[1–3] Further, the waning of symptoms is not associated with detectable development of collateral vessels.[4] Continuous hemodynamic monitoring[5–9] and pacing tests[4,10] showed that attacks at rest are not caused by an excessive increase of myocardial demand. The disparate coronary artery findings in patients with electrocardiographically documented angina at rest[11,12] and, in particular, the recurring observation that about 10% of them have no detectable coronary stenosis[13,14] lend support to the hypothesis that transient coronary obstructions caused by smooth muscle contraction or by transient intraluminal plugging by blood constituents, rather than the severity of atherosclerotic obstructions by itself, are the common denominator of the onset of angina and a sudden worsening of symptoms.

From the Cardiovascular Research Unit, Royal Postgraduate Medical School, Hammersmith Hospital, London, England.

Address for reprints: Attilio Maseri, MD, Cardiovascular Research Unit, Hammersmith Hospital, Ducane Road, London W12 OHS, England.

Dynamic stenosis occurs in some patients but not in others with comparable severity of atherosclerotic obstructions. Even in the same patient, there is variability from severe angina to improvement and even disappearance of pain for variable periods. These transient coronary obstructions are an elusive link between coronary atherosclerosis and clinical manifestations of ischemic heart disease. They are detectable at the very moment acute events take place, but not in routine angiograms or in postmortem studies. Together with the severity of fixed atherosclerotic coronary obstructions and with the impairment of contractile function, they determine both the symptoms and prognosis of ischemic heart disease.

In this report, we discuss the possible mechanisms of transient coronary obstructions, the relation between the dynamic factors and fixed atherosclerotic plaques, and their clinical implications.

The Turning Point

The major advance in our understanding of ischemic heart disease in the 1970s was the demonstration that decreased myocardial demand was not the only cause of angina.[5–9] Other mechanisms that only transiently interfere with myocardial oxygen supply can cause acute myocardial ischemia in the presence of an extremely variable degree of coronary atherosclerosis.[15] The second important finding was the angiographic observations of transient obstruction or critical narrowing of apparently normal as well as of atheromatous epicardial coronary arteries during spontaneous anginal episodes,[16] and the progressive reduction in the incidence of total coronary occlusion in the immediate hours and days after acute infarction, suggestive of early spontaneous recanalization.

Thus, routine angiographic studies performed when the patient is stable (and not during the acute episode) and postmortem examination may not necessarily reflect the state of the coronary arteries during acute events.

The problem is even more complicated in the patient with typical angina pectoris, usually exertional, who shows ischemic electrocardiographic changes, coronary sinus lactate production and pain during pacing, but has a normal coronary angiogram.[17] Such patients appear to have a reduced vasodilatory response to dipyridamole but no transient coronary obstruction. Thus, should this syndrome occur in patients who may have coronary plaques, one is tempted to attribute the cause of the ischemic episodes to these plaques without searching for other causes. The prevalence of the syndrome is unknown. Although clinically troublesome, it seems to have a good prognosis.

Fixed and Dynamic Coronary Artery Obstructions

Although either fixed or dynamic obstructions individually may be responsible for ischemic syndromes, their combination will have an enhanced influence on the symptoms and prognosis. A dynamic obstruction in a normal coronary tree is less likely to have devastating consequences than when there are multiple critical fixed obstructions. Conversely, even quite severe atherosclerotic narrowings may not cause symptoms if adequately compensated for by collaterals and if there is not an excessive increase of myocardial metabolic requirement. Under certain conditions, atherosclerotic plaques may, however, favor the development of dynamic obstructions.

Fixed Stenosis

An acute 85% diameter reduction of coronary lumen is required to reduce resting coronary flow.[18] Poststenotic pressure is reduced; this favors collateral flow. The number of collaterals and their response to pressure gradients may vary considerably among persons. Thus, the same degree of stenosis may limit considerably coronary flow reserve in patients with poor collateral development, but may be compensated for in others who have adequate collateral development, as in dogs. This difference in development of collaterals is best appreciated angiographically when the collaterals are large; it may be missed when they are small but numerous. If stenoses and collateral development were fixed, the impairment of coronary flow reserve should also be constant and ischemia would occur *only and every time* myocardial demand exceeds coronary flow reserve. Clinically, this situation should correspond to a rather fixed, predictable impairment of exercise tolerance and not to ischemia that occurs without detectable cause or at low levels of heart work.

Dynamic Stenoses

Dynamic stenoses are defined as changes in the caliber of epicardial coronary arteries that are transient, and therefore may not be detected postmortem or on routine angiography. We shall discuss the role of passive changes due to alterations in transmural pressure, of smooth muscle contraction, and of intravascular plugging.

Passive changes in vessel caliber: A recent series of studies[19,20] examined passive rather than active changes in caliber at the site of coronary stenosis in response to changes in transmural distending pressure. This mechanism, described by Burton[21] several years ago, predicts a decrease in lumen when transmural pressure is reduced and vessel closure when inflow pressure becomes lower than the critical closing pressure of the vessel. However, flow may not be influenced by the changes in lumen if the vessels are indeed collapsible.

In the absence of active tone, a reduction of outflow pressure (pressure at the venous side) in a collapsible vessel does not result in cessation of flow because a waterfall, or sluice, phenomenon takes place and the vessels behave like Starling resistors. Thus, the difference between inflow pressure and extravascular pressure at the site of the collapsible vessels becomes the driving pressure, and the level of outflow pressure becomes irrelevant as long as it is lower than extravascular pressure. In dogs with acute coronary stenosis produced with a snare to the point of preventing reactive hyperemia, a decrease in flow was observed after distal arteriolar dilatation.[22] We reproduced this phenomenon in carotid arteries of dogs without active tone only when the stenosis was produced by a snare: a decrease in flow was observed when distal pressure was reduced to low levels. The findings were opposite when comparable degrees of stenosis are produced by an intraluminal obstruction of similar degree (as it would be in the case of a subintimal plaque). We have shown that the difference in results was related to the inward protrusion of the intima caused by the snare, which is partially opposed by intraluminal pressure.[23] Also, isolated human coronary arteries with severe eccentric stenoses in the absence of active tone do not exhibit closure for levels of inflow pressure as low as 50 mm Hg, but they exhibit a waterfall phenomenon when outflow pressure is reduced. The presence of active tone will simulate, to a large extent, an increased extravascular pressure surrounding the collapsible segment. Therefore, vessel occlusion with interruption of distal flow can occur *only when smooth muscle tone results in a critical closing pressure higher than inflow pressure.* This appears unlikely unless tone increases.[24]

However, a passive wall collapse in an elastic coronary stenosis secondary to a decrease in distending pressure was recently postulated by Ganz[25] to explain vessel closure documented angiographically during spontaneous and exertional angina. This proposition appears untenable not only for the reasons discussed earlier, but also because if vascular occlusion were caused only by purely passive hydrodynamic phenomena, ischemic episodes should occur predictably every time perfusion pressure is lowered below a set level in any given patient. Nonetheless, during pacing-induced ischemia we could not find vessel occlusion in 10 consecutive patients (Fox KM, Davies GJ, Chierchia S, unpublished observations).

Coronary smooth muscle contraction: Coronary spasm has become an accepted cause of variant angina[26] and other ischemic syndromes.[27]

Recently, computerized measurements of coronary artery caliber on high-quality biplane angiography[28] have proved that at the site of severe organic narrowings, considerable coronary artery constriction can occur. This was seen during physiologic stimuli such as isometric exercise or cold pressor, and, conversely, considerable dilatation was produced by nitroglycerin. Thus, smooth muscle contraction in epicardial coronary arteries appears to be a cause of transient impairment of coronary blood supply.

As pointed out by Prinzmetal et al[29] and theoretically discussed by MacAlpin,[30] the increase of smooth muscle tone required to impair flow in a coronary artery branch could be small at the site of a subintimal plaque which already critically encroaches upon the lumen. Eccentric stenoses represent >70% of obstructions in coronary arteries, and they retain sufficient flexibility to be constricted by smooth muscle contraction.[31,32] Subintimal plaques can act as levers on the surrounding smooth muscle medial coat of the vessel so that even minimal changes in circumferential shortening can lead to a considerable reduction of the lumen. Conversely, the increase in smooth muscle tone must be considerable to impair flow in a normal segment of the vessel. On the basis of this consideration, MacAlpin suggested that normal changes in vasomotor tone may impair flow at the site of large subintimal plaques, whereas coronary spasm would more likely cause a reduction or impairment in the lumen in arteries without subintimal obstructions. On the basis of the present evidence we would, however, propose that both changes in vasomotor tone and spasm or abnormal changes in vasomotor tone can be responsible for vasoconstriction, but probably have different mechanisms.

Physiologic changes in vasomotor tone mainly control increases in flow across a stenosis at any given time and modulate the threshold for spasmogenic stimuli.[33] Increased vasomotor tone most likely contributes to the varying effort tolerance observed in patients in daily life, particularly in the cold or after meals, to the "walk-through" phenomenon, and to ischemia that occurs or worsens immediately after strenuous exercise.

We believe physiologic changes in vasomotor tone per se do not explain variant or spontaneous angina, because they are rare compared with the frequency of severe, obstructive plaques. These syndromes may occur only at certain times, and the constriction may not always occur at the site of the most severe atherosclerotic narrowing. Also, angiographic measurements during spasm do not support MacAlpin's hypothesis, because the calculated increase in tone is greater at the site of spasm than in other segments of the vessel.[34]

Coronary artery spasm may be caused by abnormal constrictive stimuli or by local supersensitivity to physiologic stimuli. These factors may explain the onset of spontaneous, unpredictable ischemic episodes more than passive changes in vessel lumen or physiologic changes in vasomotor tone alone for two reasons: (1) The spontaneous recurrence of angina interspersed with relative asymptomatic phases of the disease, so often observed in patients with angina at rest, suggest waxing and waning of some transient pathophysiologic mechanism. (2) Should passive changes in the lumen or increase in physiologic vasomotor tone play a major role per se, "spontaneous" angina should be much more frequent than is usually observed in patients with severe atherosclerotic narrowings. Although coronary artery diameter may decrease on the average by about 20% after ergonovine[35] or during handgrip exercise,[28] ergonovine is only positive in a minority of patients and only when they are in a hot phase of their disease,[36] independent of the severity of their organic coronary artery narrowings.

The mechanisms of coronary smooth muscle control are still speculative. Multiple receptors responsible for vasoconstriction have been identified in normal and in atherosclerotic segments of human coronary arteries.[37] Their role in the physiologic regulation of tone and in abnormal constriction is still poorly understood and is outside the scope of this report.

Thrombosis, thrombolysis, and platelet activation: The relationship between thrombus and myocardial infarction has been questioned on the basis of the extremely variable frequency with which postmortem studies showed a fresh occlusion in patients who died after myocardial infarction.[38] Postmortem studies represent a selection of large infarcts that are more likely to cause death and describe a static picture that may not reflect the situation at the very onset of myocardial infarction. Indeed, between the time of onset of infarction and that of the examination, thrombi can form or extend as well as undergo early lysis. Radiofibrinogen studies have indicated progressive late thrombus formation.[39,40] Conversely, angiography early after infarction showed complete vessel occlusion in 87% of cases within 4 hours of the onset of symptoms but in only 65% and in about 50% of cases when performed after 12 hours[41] and after 2 weeks,[42] respectively. The cause of occlusion and thrombus formation at a given moment in a given patient, which is the crux of the problem, remains speculative.

The mechanisms of occlusion in infarction might be related to those of spontaneous angina, because infarction is frequent in angina of recent onset or during worsening of symptoms. Also, it usually occurs in the same vascular territory that undergoes transient ischemia caused by transient spasm.[43–45]

Platelet aggregation was shown to cause transient complete vascular occlusion in dogs at the site of an acute, severe stenosis.[46,47] We observed at postmortem examination a mural thrombus composed of platelets and fibrin about 1 cm distal to the site of a complete occlusion that had been shown angiographically to be irreversible.[43] Platelet aggregation may be responsible for intraluminal plugging and may initiate thrombus formation, particularly when acute intimal damage is large, the balance between coagulation and lysis favors coagulation, and spasm is superimposed. Early lysis of thrombi or resolution of spasm, or both, can result in recanalization within a few hours or days; however, it may set the conditions for recurrent episodes of angina

pectoris caused by spasm or by transient intraluminal plugging.

Potential vicious circle: There may be a close interrelation between coronary smooth muscle constriction, intimal injury, and platelet activation and thrombosis. In normal arteries, intimal damage was documented after intense smooth muscle constriction.[48,49] In diseased arteries repeated or prolonged spasm under some circumstances may cause plaque rupture. The exposure of collagen elicits platelet activation and may initiate aggregation and thrombosis. Alternatively, platelet aggregation and thrombosis that forms because of a primitive intimal injury can result in intense coronary constriction because of the release of thromboxane A_2, serotonin and thrombin.

The repeated observation that in patients with variant angina, spasm usually occurs several times a day for long periods of time without causing permanent occlusion, and that disruption of plaques by transluminal angioplasty causes severe coronary spasm or thrombosis in only about 5% of cases, suggests the existence of protective mechanisms. Thus, a vicious circle can develop only when a set of unfavorable circumstances converge to favor intimal damage, thrombosis and smooth muscle contraction. This concurrence of unfavorable circumstances can be expected to take place only in some patients and only at a particular time, making them particularly susceptible to dynamic occlusion.

Variable susceptibility to dynamic obstructions: With the exception of angina in stationary phases, ischemic events are typically episodic. Isolated anginal attacks can occur occasionally, separated by months or years. Infarction can occur unheralded or preceded by few anginal attacks. Recent-onset angina or worsening periods begin unpredictably, sometimes rapidly culminating in infarction, but more often diminish and even disappear for months or years.[50–52] Waxing and waning periods are also common in stable exertional angina.

Should ischemic events occur as a consequence of a slow, progressive atherosclerotic narrowing, one might expect angina to appear for the first time during unusual increases of myocardial demand and, subsequently, progressively limit exercise tolerance. However, common clinical experience indicates that only occasionally does the first anginal attack occur during unusually heavy exertion; most often it occurs without apparent cause or during activities well tolerated both before and after the attack. Although it is often assumed that waning of symptoms is largely due to the development of collaterals, this possibility could not be substantiated by repeated arteriography in the study of Neill et al,[4] specifically designed to test the hypothesis.

There are several explanations as to why the individual susceptibility to dynamic obstruction may vary. First, a particular phase of the development of the atherosclerotic plaque may favor both smooth muscle contraction and intimal lesions. Second, abnormal vasoconstrictor stimuli or an increased vasomotor tone or both are most likely to occur occasionally. Finally, the increased thrombotic tendency that may favor an exaggerated response to intimal injury also seems to be transient.[53] As discussed before, these conditions may occur in 1 person but not in another, and may be present only during certain periods of life.

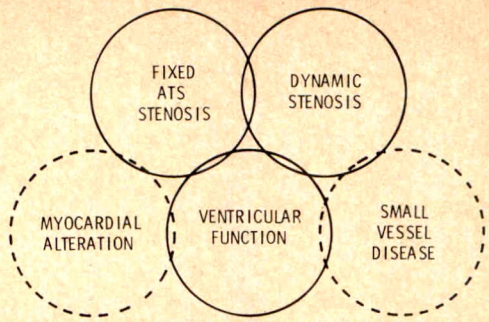

FIGURE 1. The possible determinants of prognosis and symptoms in ischemic heart disease. The major determinant of prognosis are ventricular function, the severity of fixed atherosclerotic lesions, and the susceptibility to dynamic stenoses. Hypothetical alterations of the small vessels and of myocardial metabolism may be responsible for angina but probably do not affect prognosis.

Clinical Implications

Symptoms and coronary atherosclerosis: The large variability in the relationship between severity of atherosclerotic coronary narrowings and symptoms may be explained to a considerable extent by 2 additional variables. On the 1 side, the individual response of collateral development for a given fixed stenosis conditions the severity of impairment of coronary flow reserve and, therefore, maximal exercise tolerance. On the other side, the variable susceptibility to dynamic stenosis conditions the appearance of ischemic episodes for levels of heart work, hence of myocardial oxygen requirement, which are well within the possibilities of the actual residual coronary flow reserve of the patient. This latter form of angina, also called "primary,"[54,55] may be caused also by mechanisms other than dynamic stenosis, namely by alterations of the small vessels or the myocardium or both (Fig. 1).

Determinants of prognosis: Although the relationship between severity of coronary stenosis and symptoms is quite variable, both elements appear to influence prognosis. In all published series the mortality at 5 years increases progressively with the number of diseased vessels found at arteriography, but mortality and infarction are higher among patients with unstable than with stable angina, in spite of no detectable differences in the severity of coronary atherosclerosis. We propose that this difference is largely related to the role of dynamic coronary stenoses. A greater susceptibility to dynamic stenoses could account, at least in part, for the mortality rate reported for patients with good ventricular function by Bruschke et al,[56] which was twice as high as that of the Coronary Artery Surgery Study[57] (Fig. 2). Patients referred to the Cleveland Clinic in the 1960s must have been much more symptomatic than those included in the CASS study (and not operated upon) in the 1970s. The 5-year mortality rate increases progressively with the degree of impairment of exercise

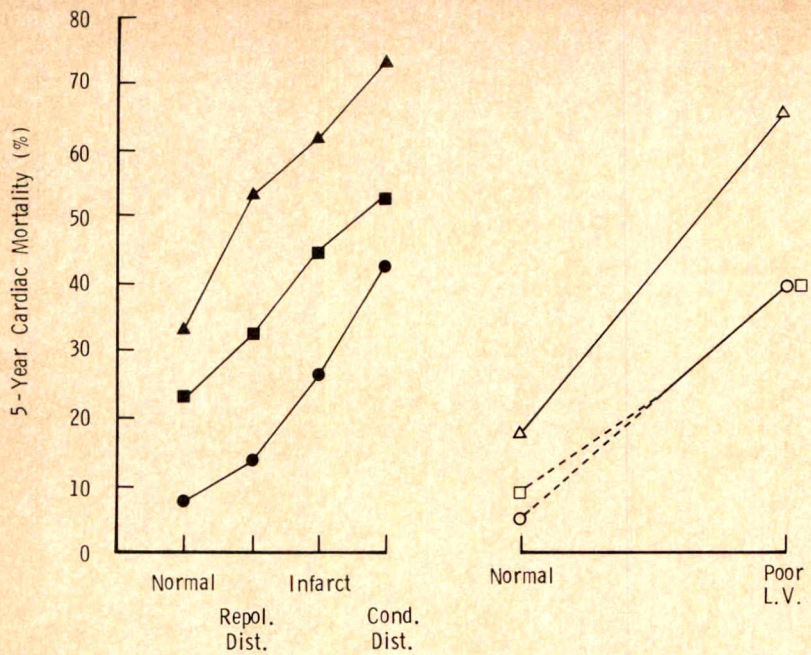

FIGURE 2. Five-year mortality in the series of Bruschke et al[56] (severely symptomatic patients, **closed symbols**) and in the Coronary Artery Surgery Study (CASS)[57] (nonoperated patients, **open symbols**). (**Circles,** 1-vessel disease; **squares,** 2-vessel disease; **triangles,** 3-vessel disease.) Although the mortality rate is similar in both studies for patients with poor left ventricular function, it is about one half in patients with normal ventricular function in the CASS study. Although the effects of changing medical therapy cannot be excluded, part of the difference may be that the patients in the series of Bruschke et al[56] were more symptomatic for comparable severity of coronary atherosclerosis because of greater susceptibility to dynamic obstructions.

tolerance assessed by stress testing[58]; we interpret this as a more severe fixed impairment of coronary flow reserve (resulting from the balance between severity of stenoses and development of collaterals).

Therefore, among patients with good ventricular function, it may become possible to identify subsets with an unfavorable prognosis because of poorer collateral development, greater susceptibility to dynamic obstructions, or both. The role of these prognostic determinants may be obscured by the presence of poor left ventricular function, which is, by itself, the major determinant of prognosis and was not appreciably different in the series of Bruschke et al[56] and in the Coronary Artery Surgery Study.[57]

Rational basis for therapy and prevention: Therapy of angina is still largely dominated by the primary aim of reducing myocardial oxygen requirements. The favorable response to beta blockers is used to validate this concept, but it is naive to assume that beta blockers have only this effect or that they act only through this mechanism. This attitude is reminiscent of that in the 1950s, when nitrates were thought to be effective because they increased myocardial blood flow. The hypothesis of an increase of myocardial demand exceeding coronary flow reserve was not supported by objective measurements, not only in patients with angina at rest but also for most episodes that occur during ambulatory monitoring of the electrocardiogram[59,60] in patients with stable angina. Thus, a *transient* impairment of myocardial oxygen supply may play a dominant role in angina. The role of dynamic stenosis in angina is beginning to be appreciated,[61,62] but it may have multiple mechanisms.[63] The identification of the role and varied mechanisms of dynamic stenoses help prevent anginal attacks caused by a transient impairment of flow rather than by an excessive increase of demand.

The prevention of dynamic stenoses and the assessment of coronary flow reserve by stress testing should help to identify the subset of patients who will benefit most from revascularization.

Responses of Dog Large Coronary Arteries to Constrictor and Dilator Substances: Implications for the Cause and Treatment of Variant Angina Pectoris

JAMES A. ANGUS, PhD, ROBERT M. BRAZENOR, PhD, and MATTHEW A. Le DUC

Canine circumflex coronary artery ring segments were mounted in organ baths and contracted by ergonovine (ergometrine), serotonin, phenylephrine, norepinephrine (in the presence of propranolol), potassium (K^+) and a thromboxane A_2 mimetic, U46619. Ergometrine was classified as a serotonin agonist since concentration-response curves were competitively inhibited by methysergide but not by alpha-adrenoceptor antagonists. Arteries precontracted to 80% of maximum were relaxed by verapamil, nifedipine and glyceryl trinitrate. However, nifedipine was 100-fold more potent against K^+ than either serotonin- or phenylephrine-contracted vessels. Verapamil showed some selectivity for K^+ and serotonin contractions compared with phenylephrine and was almost ineffective against U46619. Glyceryl trinitrate was without selectivity. Electrical field stimulation (2 and 20 Hz, 10-second) caused a weak contraction or relaxation or biphasic response in the isolated coronary ring. Contraction was amplified by propranolol (up to 1 μM) or metoprolol (50 ng/ml) and inhibited by alpha-adrenoceptor antagonists. In a blood-perfused left anterior descending coronary artery preparation, external diameter was measured by sonomicrometry under conditions of controlled flow and resistance. Intra-arterial serotonin, U46619 and ergometrine infusions decreased the diameter by up to 18% without causing spasm (0 lumen diameter). Lowering the perfusion pressure from 90 to 60 mm Hg increased the decrease in diameter during serotonin infusions. Verapamil (50 to 150 ng/ml) and nifedipine (15 to 45 ng/ml) inhibited, to a similar degree, the decrease in coronary artery diameter in response to serotonin infusions. However, verapamil was more effective than nifedipine in depressing the sinoatrial node, abolishing reflex tachycardia and lengthening the atrioventricular conduction time. These studies suggest that verapamil and nifedipine are only selective antagonists of constrictor agents in the dog coronary artery, that both low perfusion pressure and beta-adrenoceptor blockade may amplify constrictor responses, and that nifedipine has fewer cardiotoxic effects than verapamil.

Large coronary arteries decrease in luminal diameter by a maximum of about 20% during intravenous ergonovine (ergometrine) administration in man,[1] or methoxamine[2] or stellate ganglion stimulation in dogs.[3] This weak vasoconstriction of the large conduit vessels would not normally be sufficient to reduce coronary blood flow and induce angina. However, in some patients with Prinzmetal's variant angina,[4] the ergonovine provocative test may induce complete coronary artery occlusion (vasospasm), often at the site of a minimal organic lesion.[5,6] Although this clinical test is useful in demonstrating that spasm can occur, it does not necessarily help to identify the cause of vasospasm that occur spontaneously. At least 2 factors may be involved in vasospasm. First, a constrictor substance such as norepinephrine released from sympathetic nerve terminals, or serotonin or thromboxane A_2 released from platelets could initiate focal vasoconstriction. Second, this constrictor stimulus would require an amplifier before vasospasm occurs.

We investigated the reactivity of dog large coronary artery segments to sympathetic nerve stimulation and to a range of vasoconstrictor substances. Interactions of verapamil, nifedipine and glyceryl trinitrate with various vasoconstrictors were also assessed. Experiments were performed in isolated coronary artery ring segments in which changes in circumferential force were measured, and in a blood-perfused left anterior descending coronary artery (LAD) in which external diameter was measured by sonomicrometry. These 2 approaches have provided an insight into the variation of coronary constrictor agents in their requirement for extracellular calcium, suggested 2 factors other than fixed lesion that may amplify constrictor responses, and highlighted some differences in the cardiovascular properties of verapamil and nifedipine.

Methods

Isolated coronary artery ring segments: Greyhound dogs (20 to 25 kg) of either sex were anesthetized with sodium pentobarbital (40 mg/kg, intravenously). The chest was opened and the heart removed. Approximately 4 cm of the proximal circumflex coronary artery was cleared of connective tissue and cut into 3-mm-long ring segments. The segments were suspended in a jacketed organ bath by 2 stainless-steel hooks; the lower hook connected directly to an isometric force displacement transducer (Grass FTO3C). The 30-ml organ baths contained a solution of a composition (in m*M*) of Na^+ 144, K^+ 5.9, Ca^{++} 2.5, Mg^{++} 1.2, Cl^- 128.7, HCO_3^- 25, SO_4^{--} 1.2, $H_2PO_4^-$ 1.2, and glucose II at 37°C, aerated with a gas mixture of 95% oxygen and 5% carbon dioxide. An initial force of 4 *g* was applied and readjusted to this level 30 minutes later if necessary. As many as 12 ring segments were cut from each circumflex artery and 6 rings were used concurrently.

After 60 minutes of equilibration, concentration-response curves were constructed by the cumulative addition (0.5 log unit increments) of constrictor substance until the maximal response was achieved. Alternatively, concentrations of verapamil or serotonin antagonists were left in contact with the tissue during the 60-minute equilibration period. In all experiments, only a single concentration-response curve with or without antagonist was obtained in each segment. The advantages of this design have been discussed previously.[7] In a second series of experiments, ring segments were constricted by a single concentration of agonist chosen to cause approximately 80% of the maximal response to that drug. When the constriction had reached a plateau, the ring segments were relaxed toward the preconstricted level by the cumulative addition of verapamil, nifedipine or glyceryl trinitrate.

Responses to sympathetic nerve stimulation were measured after square-wave monophasic electrical field pulses (2 or 20 Hz, 2 ms duration, 10 V/cm) (Grass SD9) for 10 seconds delivered from platinum field electrodes placed either side of the coronary ring segment. The field pulses were monitored on an oscilloscope. Only 2 periods of 2- and 20-Hz field stimulation were given to any 1 ring segment, the second period after 30-minute equilibration with propranolol, metoprolol or phentolamine. Some segments were pretreated with an irreversible alpha-adrenoceptor antagonist (benextramine) or propranolol before the first period of field stimulation.

Measurement of coronary artery diameter: A 5-cm length of LAD together with a 3-cm-wide portion of the surrounding myocardium was separated from a dog heart immediately after its removal from an anesthetized greyhound. The tissue was immersed in cold oxygenated Krebs' solution (see coronary ring method). The LAD was cannulated near its origin and again 3 to 4 cm distal. A small catheter was placed in a side branch of the LAD to monitor intraluminal perfusion pressure. Heparinized femoral arterial blood from an anesthetized support dog (pentobarbitone, 30 mg/kg intravenously and 6 mg/kg/h) was pumped (Watson-Marlow) through the coronary artery segment at 50 ml/min and then through a pneumatic Starling resistance before being returned to the femoral vein of the support dog (Fig. 1).

Continuous phasic external coronary artery diameter was measured by the transit-time ultrasound technique.[8] With minimal dissection, a small, lightweight piezoelectric receiver crystal (1.5 mm × 3 mm, 5.4 mg) was placed beneath the LAD. A second emitter crystal (9 MHz) of similar dimensions was glued to the upper surface of the LAD (directly above the receiver crystal) with a small amount of tissue adhesive (cyanoacrylate, Eastman Kodak 910). The accuracy, linearity and stability of the entire system resolves changes in diameter of <0.01 mm and does not drift over long periods.

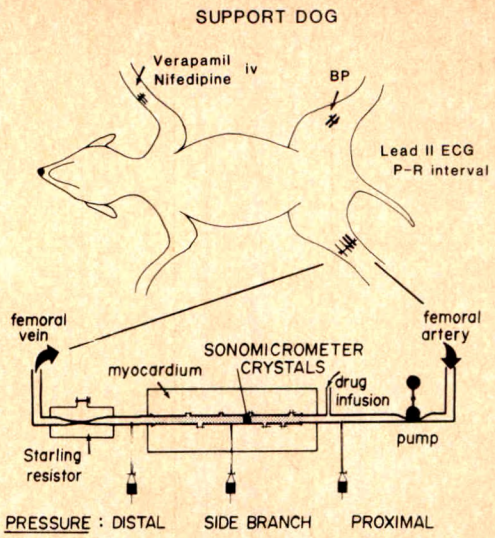

FIGURE 1. The in vivo experiments in which the arterial blood from a support dog was used to perfuse the left anterior descending coronary artery from another heart under conditions of controlled flow and resistance. BP = blood pressure.

The surrounding myocardium was clamped to limit the perfusion of the coronary resistance vessels as much as possible. When this perfusion did occur, the venous blood was collected in a polyethylene tray and returned to the supporting dog. Serotonin (or saline solution) was infused (at 1 ml/min by roller pump) directly into the coronary artery by a side-hole catheter in the proximal cannula. This procedure allowed cumulative concentration-response curves to be readily obtained by changing the concentration of the serotonin infusion in 10 ml vials. The proximal and distal perfusion pressures were monitored from side ports (Fig. 1). Mean and phasic LAD external diameters were continuously measured. Hemodynamic measurements from the support dog included aortic blood pressure from a catheter advanced from the femoral artery and heart rate and the PR interval from the lead II electrocardiogram run at 100 mm/s chart speed. During verapamil experiments, a bipolar pacing catheter (USCI-No. 6F) was inserted into the right ventricle through the external jugular vein. The effect of verapamil and nifedipine as vasodilators in the large coronary artery was evaluated by the degree of blockade of serotonin concentration-response curves. After the intracoronary infusion of serotonin, (±) verapamil was given by bolus and infusion intravenously to the support dog to increase the plasma level to 50, 150 and 500 mg/ml. The plasma levels were not measured, but were calculated from the first-order kinetics of verapamil in dogs.[9] The actual doses were 0.67, 1.56 and 4.47 mg/kg given slowly over 5 minutes, followed by infusions of 9.3, 31, and 93 μg/kg/min for 50, 150, and 500 ng/ml levels, respectively. After 10-minute infusion of each level of verapamil, the serotonin concentration-response curve was started. A similar protocol was followed for nifedipine except that only intravenous bolus injections were given to the support dog, since this drug has a long half-life compared with verapamil (150 to 180 versus 15 to 30 minutes).[10] Doses of nifedipine were 15, 45 and 150 μg/kg.

At the end of each experiment, a double-bladed scalpel was used to remove a 4.33-mm length of LAD taken from the area of the sonomicrometer crystals. From the weight of this segment (W) and the tissue density (1.06), the wall volume (Vw)

was calculated as Vw = W/1.06. The internal radius (Ri) was calculated from $Ri^2 = Re^2 - (Vw/II.L)$, where Re is the external radius.

Drugs were freshly prepared daily and diluted in distilled water. Drugs used were benextramine tetrahydrochloride, methysergide bimaleate, and pizotifen malate, (−) noradrenaline bitartrate dissolved in ascorbic acid, 0.1 n*M*, phenylephrine hydrochloride, cyproheptadine hydrochloride, (±) propranolol hydrochloride, prazosin hydrochloride, ergometrine maleate, serotonin creatinine sulphate, (±) verapamil, U46619 (15 S-hydroxy-9α,-11α-(epoxymethano) prosta-5Z 13E-dienoic acid) and glycerol trinitrate; nifedipine was dissolved in polyethylene glycol 300 and protected from light.

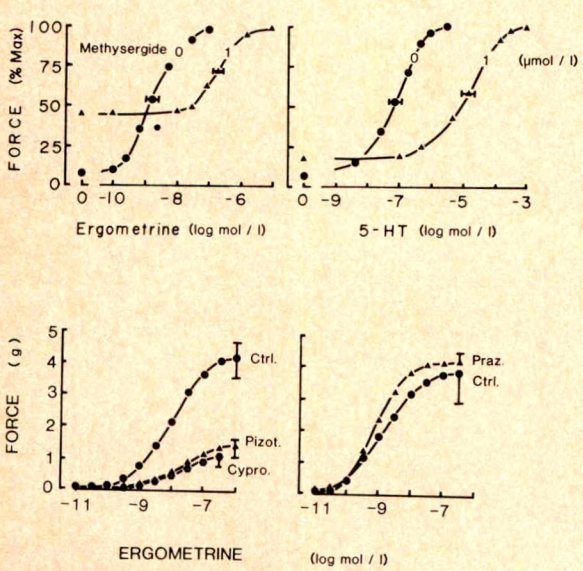

FIGURE 3. Concentration-response curves to ergometrine and serotonin (5-HT) in isolated coronary ring segments. **Top,** methysergide (1 μM) was a competitive antagonist of both ergometrine and 5-HT. **Bottom,** pizotifen (pizot) and cyproheptadine (cypro) (1 μM) were noncompetitive antagonists. Prazosin (pra), 10 n*M*, failed to antagonize ergometrine concentration-response curves. Error bars are ±1 standard error for 5 to 7 rings. ctrl = control.

Results

Isolated coronary ring segments: *Constrictor substances:* The most potent constrictor substance found on the circumflex coronary ring segment was ergonovine (ergometrine) (Fig. 2). However, the magnitude of the maximal response was substantially less than either serotonin (5HT) or a thromboxane A_2 mimetic drug, U44619. Norepinephrine in the presence of propranolol was similar (although less potent) to ergometrine in terms of magnitude. Phenylephrine, a more selective alpha-adrenoceptor agonist, was similar to norepinephrine.

The receptor mediating the response to ergometrine was classified as a serotonin receptor and not an alpha-adrenoceptor from the following observations.

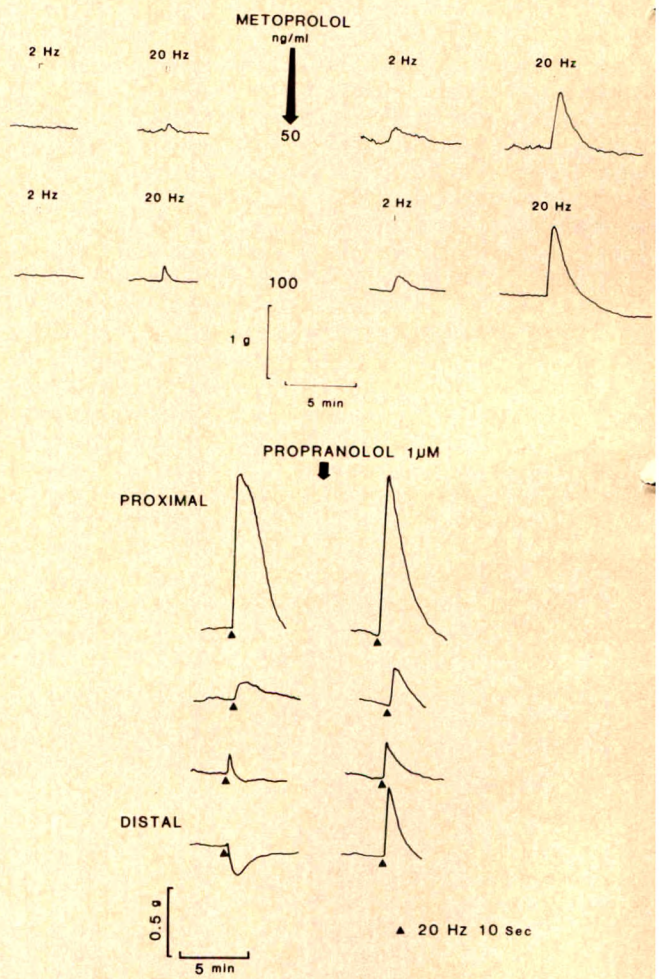

FIGURE 4. Traces from isolated coronary ring segments during electrical field stimulation (2 or 20 Hz, 10 seconds). **Top,** metoprolol experiments. Two rings from 1 circumflex coronary artery before (**left**) and in the presence (**right**) of metoprolol, 50 ng/ml (top ring) and 100 ng/ml (bottom ring). **Bottom,** traces from 4 rings from 1 circumflex coronary artery (15 mm long) arranged in order from proximal to distal, showing different responses to 20-Hz field stimulation. **Left,** control responses; **right,** in the presence of propranolol, 1 μM.

In guinea pig aorta, a tissue responsive to alpha-adrenoceptor stimulation, both ergometrine and serotonin were inactive (up to 1 μM). In dog coronary artery, the specific alpha-adrenoceptor antagonist prazosin, or the irreversible alpha-adrenoceptor antagonist benextramine, failed to block the response to ergometrine (Fig. 3). More precision was achieved with serotonin antagonists. Methysergide was the only antagonist that has been claimed to block serotonin receptors that displaced the ergometrine and serotonin concentration-response curves in parallel without reduction in maximum. The estimated dissociation constant (K_B) for methysergide was similar for ergometrine and serotonin as agonists (13 and 10.2 nM), indicating that ergometrine was a serotonin receptor agonist in this tissue.[11] Methysergide was also a constrictor substance itself in these experiments (partial agonist), as shown by the increase in baseline before the commencement of the agonist curves (Fig. 3). In contrast, other serotonin antagonists, pizotifen and cyproheptadine (1 μM), were noncompetitive antagonists of ergometrine without causing a constrictor response on their own (Fig. 3).

Sympathetic nerve stimulation: Ring segments cut from a single 3-cm length of circumflex coronary artery often responded differently to electrical field stimulation. Some segments contracted and others relaxed, but most showed a biphasic response pattern of early constriction followed by more prolonged relaxation (Fig. 4). The responses were mediated by norepinephrine released from sympathetic nerves, since a combination of propranolol (1 μM) and phentolamine (1 μM) completely abolished all responses as did the Na^+ channel blocker tetrodotoxin (0.1 to 1 μM). In segments pretreated with the irreversible alpha-adrenoceptor antagonist benextramine, only marked relaxation was observed to field stimulation, a response that was subsequently blocked by propranolol (Fig. 5). In arteries pretreated with propranolol (1 μM) or metoprolol (50 to 100 ng/ml, a concentration observed in the plasma of patients in treatment for exercise-induced angina), the constrictor response was enhanced (Fig. 4 and 5). These findings emphasize that large coronary arteries are neurally innervated and that responses may be mediated by alpha- or beta-adrenoceptors or both.

Vasodilator substances: In the isolated ring segments, the specificity of the dilator action of verapamil,

Control (alpha- + beta-adrenoceptors), n = 7; benextramine 10 μM (beta-adrenoceptors only), n = 8; propranolol 1 μM (α-adrenoceptors only), n = 4. Error bars are ±1 standard error.

nifedipine and glyceryl trinitrate was compared in arteries contracted submaximally with K^+, (25 mM), serotonin (0.3 μM), phenylephrine (1 μM), and the thromboxane A_2 mimetic U44619 (0.03 μM). Glyceryl trinitrate relaxed the arteries with a similar IC_{50} value (concentration giving 50% inhibition of contraction) for each of the 4 constrictor agents (Fig. 6). In contrast, the slow calcium-channel blockers nifedipine and verapamil showed marked differences in their ability to relax arteries contracted by the 4 constrictor substances. Nifedipine was very potent against K^+ depolarized arteries ($IC_{50} = 8.5 \times 10^{-9} M$) but was relatively weak against both serotonin ($IC_{50} = 1.8 \times 10^{-6} M$) and phenylephrine ($IC_{50} = 1.7 \times 10^{-6} M$) contracted arteries. Verapamil was much weaker than nifedipine against K^+ ($IC_{50} = 1.1 \times 10^{-6} M$), but was similar against serotonin ($IC_{50} = 1.5 \times 10^{-6} M$). Verapamil was 4-fold more potent against serotonin-contracted tissues than against phenylephrine. However, in contrast to glyceryl trinitrate, verapamil was extremely ineffective against coronary rings contracted by U46619. This difference could not be accounted for by different absolute starting levels of constriction, since glyceryl trinitrate was equally ef-

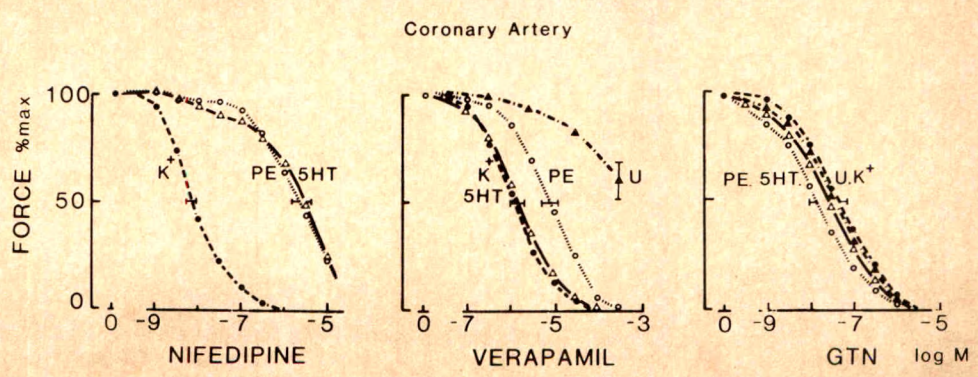

FIGURE 6. Relaxant effects of nifedipine, verapamil, and glyceryl trinitrate (GTN) in isolated coronary artery rings contracted by K^+ (25 mM), phenylephrine (PE, 1 μM), serotonin (5HT, 0.3 μM), or thromboxane A_2 mimetic (U46619, 0.03 μM). **Ordinate,** change in force, percentage of maximal response to constrictor agent; **abscissa,** concentration of dilator agent (log scale). Horizontal error bars are ±1 standard error at IC_{50} (concentration giving 50% inhibition of contraction) for ≥6 rings in each curve. Only 1 curve was obtained in each ring.

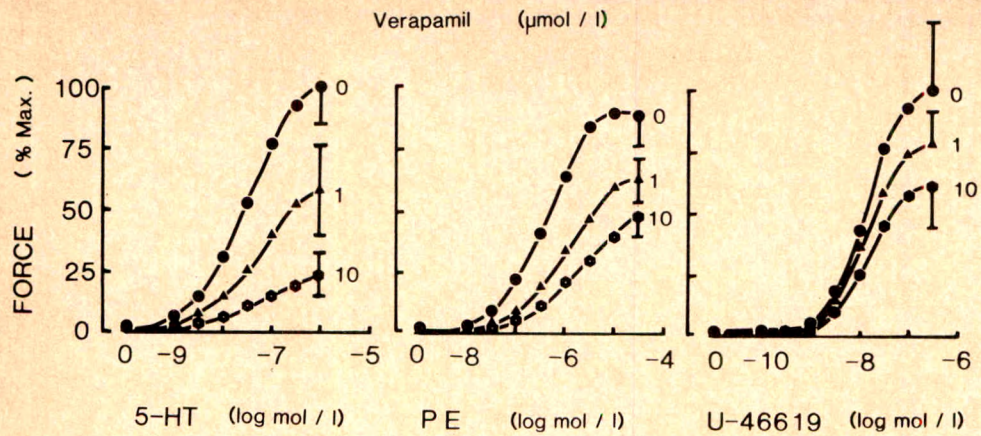

FIGURE 7. Effects of verapamil (0, 1 and 10 μM, 60-minute contact) on vasoconstrictor responses to serotonin (5-HT), phenylephrine (PE) and the thromboxane A_2 mimetic U46619 in isolated coronary ring segments. Only 1 concentration-response curve was obtained in each ring. Values are mean ±1 standard error, with at least 5 tissues per verapamil concentration.

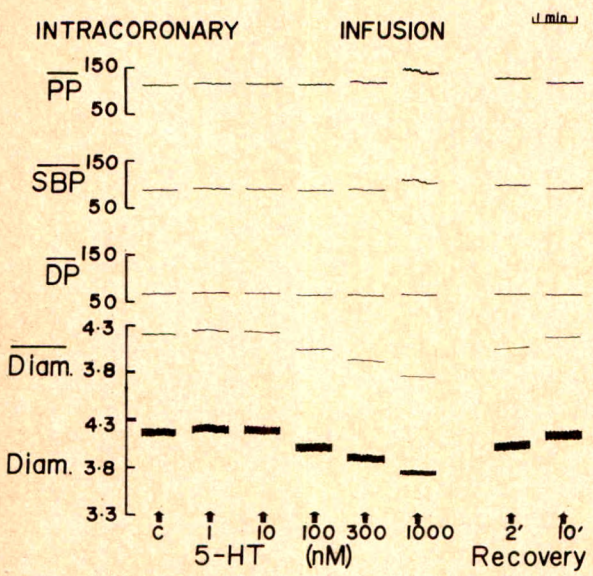

FIGURE 8. Hemodynamic measurements during intracoronary infusions of serotonin (5-HT). From top, the records are mean proximal perfusion pressure (PP), mean side branch pressure (SBP), mean distal pressure (DP), mean (DIAM) and phasic (DIAM) external coronary artery diameter. All units of pressure are in millimeters of mercury and diameter is in millimeters. Recovery traces are shown at right.

fective against the same concentration of constrictor agents.

In a different experimental design in which verapamil was equilibrated with the artery before the addition of the constrictor agent, a similar pattern was noted (Fig. 7); that is, verapamil (1, 10 μM) was more effective against serotonin concentration-response curves than against phenylephrine. The poor inhibition by verapamil of the response curve to U46619 may suggest that this constrictor does not require extracellular Ca^{++} for contraction. In 6 coronary rings equilibrated for 45 minutes in Ca^{++}-free Krebs' solution, serotonin and phenylephrine failed to elicit a contraction, while U46619 was still most effective (80% of normal).

Diameter measurements in situ: *Pressure-diameter relationship, serotonin, U46619, ergometrine:* The relationship of intraluminal pressure (measured from side branch in the LAD) to luminal diameter of the coronary artery was curvilinear, the artery showing greater passive changes in diameter in pressures from 50 to 100 mm Hg than from 100 to 150 mm Hg. In each preparation, the pressure/diameter type curve was determined by varying the pressure in the Starling resistor. Intracoronary serotonin infusions at a side branch pressure of 90 mm Hg lowered the external diameter, calculated internal diameter and area in a concentration-dependent manner (Fig. 8 and 9). The decrease in diameter was clearly an active response to the serotonin and was not due to a decrease in luminal pressure, emphasizing an advantage of this preparation in defining the magnitude of diameter change in large coronary vessels. The diameter returned rapidly to preinfusion levels when the serotonin was replaced by 0.9% sodium chloride. Serotonin infusions did not alter the hemodynamics in the support dog, presumably because the metabolism of serotonin through the lungs and dilution on entering the femoral vein. Intracoronary infusions of U46619 up to 1 μM caused a decrease in diameter similar to serotonin, but was approximately 3-fold more potent. At 0.3 and 1 μM, U46619 caused marked cardiovascular changes in the support dog including hypertension, tachycardia and an increase in central venous pressure. Ergometrine (1 to 1000 nM) caused a maximal decrease in luminal diameter of only 12%, about half that of serotonin. The recovery of diameter after stopping U46619 was approximately 30 minutes, and >1 hour after ergometrine. We never observed a decrease in luminal diameter of >40% for any of these constrictor substances.

Amplification of constriction: The effect of perfusion pressure on the magnitude of the decrease in diameter to serotonin infusions was examined. In each artery complete concentration-response curves to serotonin were obtained at 60 and 90 mm Hg intraluminal pressure. These pressures were set before the infusion of serotonin by adjustment to the Starling resistance. The diameter decreased to a lower level during serotonin infusions with 60 mm Hg perfusion pressure, principally because the starting diameter was lower than at 90 mm Hg (Fig. 9). No significant change was observed in the potency of serotonin.

Simple geometric considerations of the effect of luminal encroachment by 20 to 40% (as in atheromatous

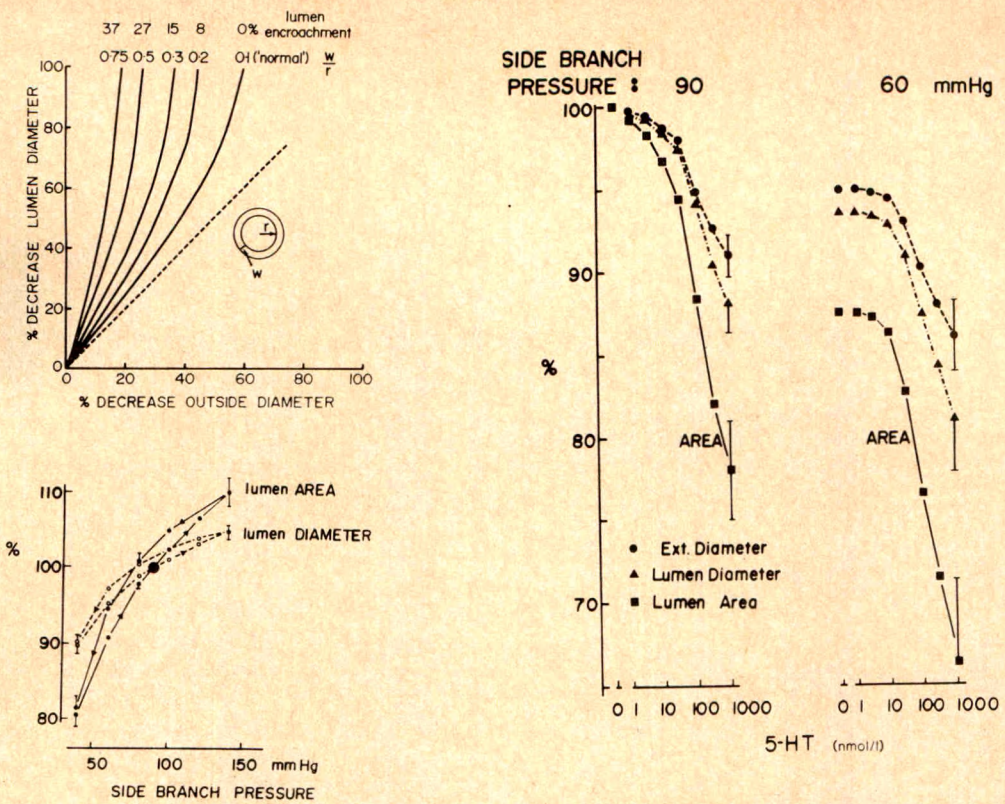

FIGURE 9. Left top, theoretical relation between percent changes in outside diameter and percent change in luminal diameter of a coronary artery when the ratio of wall thickness to lumen radius varies from 0.1 to 0.75. If the ratio of 0.1 is taken as a normal artery, the percent luminal encroachment at rest is calculated for the higher ratio. Adapted from MacAlpin.[33] **Left bottom,** effect of altering perfusion pressure on the luminal diameter and luminal area. Measurements were calculated as percentage of values at 90 mm Hg. **Right,** effect of perfusion pressure (90 mm Hg left, 60 mm Hg right) on the magnitude of decrease in coronary artery diameter during intracoronary serotonin (5-HT) infusions. External and internal diameter and luminal area were measured as percentage of value at 90 mm Hg before the start of the serotonin infusion. Values are mean ± standard error in 10 arteries. Both curves were completed in each artery.

lesions or by wall thickening) suggest that relatively small decreases in diameter (20%) should be sufficient to reduce the luminal diameter to almost 0 (Fig. 9).

Comparison of verapamil and nifedipine in vivo: Full serotonin concentration-response curves could be readily repeated up to 4 times in the blood-perfused LAD preparation. The maximal decrease in luminal area from preinfusion level was 20 to 25%. As the concentration was increased further, the diameter started to return toward control (Fig. 10). If the maximal decrease in luminal area for the first concentration-response curve to serotonin was considered to be 100%, the second and third curves repeated in the same artery were virtually identical in sensitivity and magnitude (Fig. 11). In support dogs without calcium-channel blocker, systemic blood pressure decreased gradually (by 19 mm Hg) over 5 hours, the period in which 4 serotonin-response curves were completed. The heart rate and PR interval remained steady throughout this period (Fig. 12). In contrast, both nifedipine and verapamil lowered blood pressure in a concentration-dependent fashion. Heart rate was elevated by nifedipine administration but was reduced substantially by verapamil (Fig. 12). Atrioventricular conduction was unaffected by the lower concentrations (15, 45 ng/ml) of nifedipine, whereas verapamil caused marked increase in PR interval even with the first concentration (50 ng/ml). With

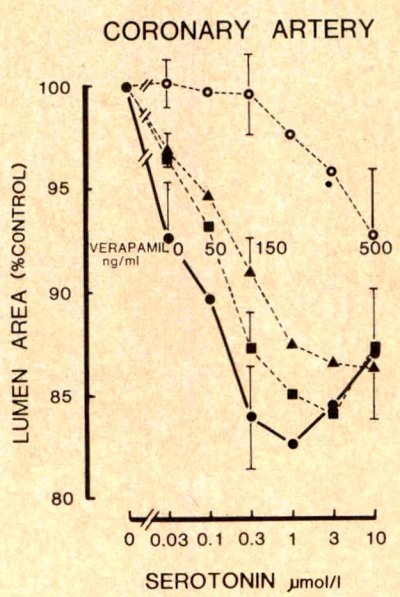

FIGURE 10. Effect of verapamil on constrictor responses to serotonin in blood-perfused left anterior descending coronary artery. Verapamil was given by intravenous bolus and infusion to the support dog to give plasma levels calculated to be 50, 150, and 500 ng/ml. Each artery (n = 8) had 0 and 50 ng/ml verapamil, but only 7 and 5 of these, respectively, had 150 and 500 ng/ml. Responses were calculated as luminal area, taking control values at the start of each serotonin curve as 100%.

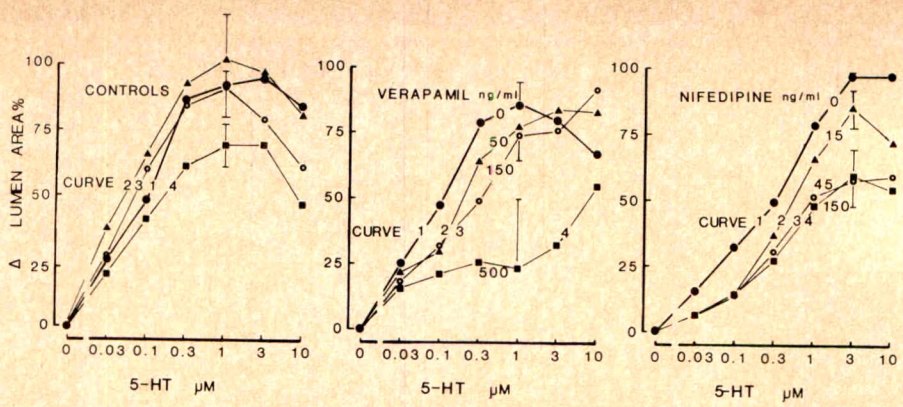

FIGURE 11. Effect of verapamil and nifedipine on constrictor responses to serotonin (5-HT) infusions in the perfused left anterior descending corona artery. **Ordinate,** decrease in luminal area as a percentage of the maximal decrease to serotonin observed in the first curve in each artery. Subsequ curves (2, 3, and 4) were obtained without antagonist (**left**), or in the presence of verapamil (50 to 500 ng/ml, **middle**) or nifedipine (15 to 150 ng/ **right**). Both antagonists were administered to the support dog. Error bars are ±1 standard error. Controls, n = 5; verapamil, n = 5 to 8; nifedipi n = 6.

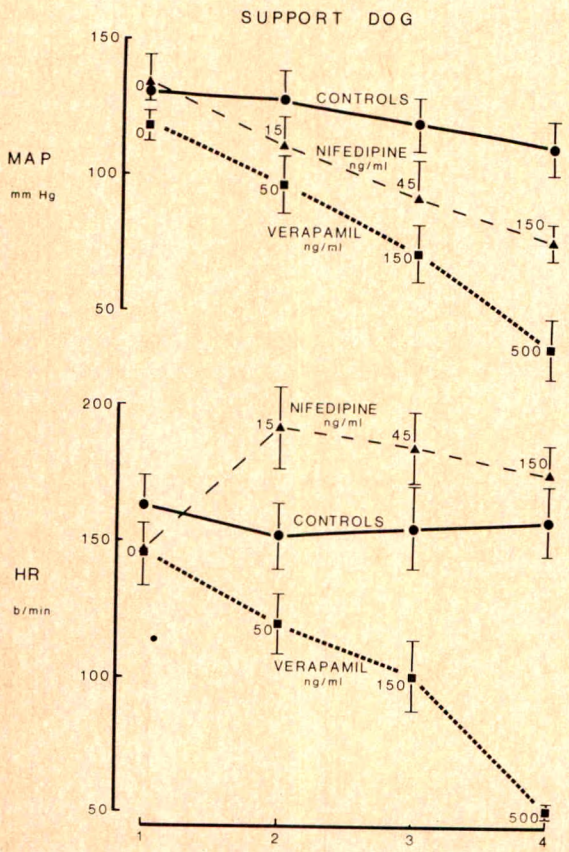

FIGURE 12. Mean arterial pressure (MAP) and heart rate (HR) values for the support dogs during the 4 serotonin infusions (numbers 1 to 4 on **abscissa**). There were 3 groups of dogs; control, **circles;** nifedipine, **triangles;** and verapamil, **squares.** The concentrations of calcium antagonists are shown. Error bars are ±1 standard error.

150 ng/ml of verapamil, 5 of 7 dogs had atrioventricular block (Fig. 13). The range of concentrations of both verapamil and nifedipine were closely matched in their ability to reduce the coronary constrictor response to serotonin (Fig. 11). With the lower concentrations of verapamil (curve 2 and 3), the decrease in diamet during serotonin infusions was less than that during t control curve. Nifedipine also lowered the sensitivi of the coronary artery to serotonin and reduced t maximal constrictor response, a response compatib with the concentration-response curves in the isolat coronary ring (Fig. 7).

Discussion

In these experiments we have qualified the potenc and magnitude of a variety of constrictor substances o the coronary artery in the controlled environment of t organ bath where neural, hormonal and metabol changes can be eliminated. In the blood-perfused LA preparation, we could determine direct effects of co strictors and antagonists on coronary diameter witho the influences of blood flow and pressure change Therefore, these 2 preparations have allowed a mo rigorous analysis of the responses of the large coronar artery than is possible in man or in the intact myoca dium in experimental animals.[2]

Vasospasm: Vasospasm, defined as 0 luminal di ameter, was not observed in the experimental prepa rations of the LAD during infusion of high concentra tions of constrictor agents. The maximal decrease i luminal diameter was about 20 to 30%, a reduction tha would be unlikely to influence flow, especially if th constriction was confined to a few isolated sites. How ever, these dog coronary arteries were essentially nor mal, without atheromatous lesions, and were denervate by removal from the donor dog. Under appropriat conditions, one may be able to observe vasospasm ini tiated by a relatively small decrease in luminal diameter Such an amplified response could occur at sites of rel atively small atheromatous lesions,[6,12] where lumina encroachment or medial hypertrophy would lead to a greater decrease in luminal diameter for a given con strictor stimulus.

Another factor that may amplify the response t constrictor stimuli is low coronary pressure. Our ex periments show that the diameter of a large coronary artery decreases to a significantly lower level in the

presence of a constrictor substance when the perfusion pressure was reduced from 90 to 60 mm Hg. Therefore, 1 explanation of recurrent nocturnal pain that[13] wakes patients from sleep (13 of 17 patients, all with rest pain) could be that lower arterial pressure during sleep amplifies the constrictor response to some stimuli.

Possible mediators of coronary spasm: Experiments on isolated coronary rings suggest that ergometrine is a potent coronary artery constrictor substance acting as a serotonin agonist.[11] Similar conclusions have been reported previously.[14,15] The specificity of ergometrine as a diagnostic agent in variant angina may indicate a role for serotonin, perhaps released from platelets at the site of a minimal lesion. Platelets also produce thromboxane A_2(TxA_2), a product of arachidonic acid metabolism that is a powerful vasoconstrictor agent and an inducer of both platelet aggregation and the platelet release reaction.[16] TxA_2 is very unstable, at 37° at pH 7.5 with a half-life of 30 seconds, making it very difficult to define responses quantitatively. Therefore, we used the stable analog of TxA_2, U46619, which has a potent constrictor action similar to TxA_2 in human and dog coronary artery.[17,18] Although TxA_2 is a candidate for initiating vasospasm, clinical trials with synthesis inhibitors have been disappointing.[19]

Norepinephrine may also be a trigger stimulus for vasospasm. Coronary artery ring segments, however, did not contract consistently to this catecholamine added to the organ bath unless beta-adrenoceptor blockade was present. In the perfused coronary artery, norepinephrine infused into the lumen caused a small increase in diameter, which was also blocked by propranolol. These experiments do not support a role for circulating catecholamines in initiating coronary constriction. However, sympathetic nerve stimulation experiments may provide a clue to neurogenic vasospasm. Adjacent 3-mm segments from the circumflex coronary artery react very differently both in direction and magnitude of response to 10-second periods of stimulation. Therefore, it may be possible for a small segment to respond with marked constriction, although adjacent segments are less responsive. The receptors stimulated by the released norepinephrine are clearly alpha- and beta-adrenoceptors, as seen from the effects of the antagonists phentolamine and propranolol. Moreover, the density and type of adrenoceptor may vary along a large artery.

Because beta-adrenoceptors are apparently innervated in large coronary arteries, the use of beta-adrenoceptor antagonists could raise the incidence of episodes of variant angina by reducing neurogenic dilator tone. Indeed, this has been reported for propranolol in a small number of patients in a recent trial.[20] Theoretically, if beta-adrenoceptors in coronary arteries were of the $beta_2$ subclass, then a selective $beta_1$-adrenoceptor antagonist may still be useful in the treatment of variant angina.[21] This does not appear to be the case for large coronary arteries, at least from the dog, where agonist and antagonist studies showed some evidence for a $beta_1$-adrenoceptor classification.[22] Our studies showed that the so-called selective $beta_1$-adrenoceptor antagonist metropolol[23] amplified the constrictor response to sympathetic stimulation. We deliberately chose a concentration of metoprolol (50 ng/ml) that was within the range of peak plasma levels (20 to 198 ng/ml) observed in patients receiving metoprolol therapy for typical angina pectoris.[24,25] Therefore, beta-adrenoceptor blockade with nonselective or selective ($beta_1$) adrenoceptor antagonists may also act as an amplifier of focal neurogenic vasoconstriction.

Nifedipine, verapamil, and glyceryl trinitrate: Constrictor substances may vary in their requirement

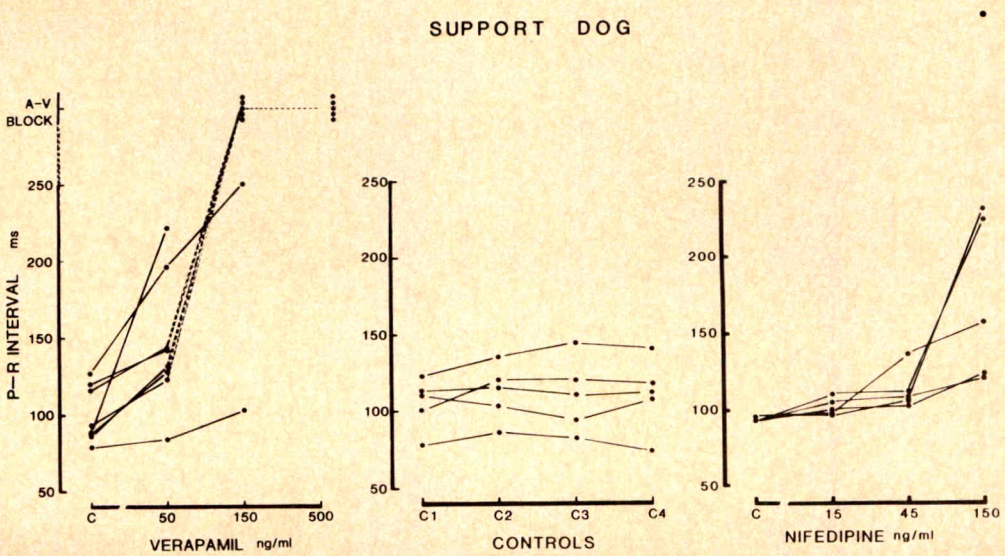

FIGURE 13. Effect of verapamil and nifedipine on the atrioventricular conduction (P-R interval in milliseconds) in the support dog. Each line represents the value for 1 experiment. Readings are the average of 3 to 6 intervals measured from lead II electrocardiogram, recorded just before the start of each of 4 serotonin curves.

for extracellular and intracellular calcium for activating contraction. Therefore, if dilator agents act by blocking the slow calcium channel without affecting the calcium release from intracellular stores, then only constrictors dependent on extracellular calcium should be sensitive to these antagonists. Both verapamil and nifedipine are classed as slow calcium channel blockers,[10,26,27] so they should have similar relative potencies against a range of constrictor agents. This is clearly not the case in the present studies, since nifedipine was 100-fold more potent against potassium-depolarized arteries than against serotonin or phenylephrine, whereas verapamil was similar in potency against serotonin and potassium but 3-fold less potent against phenylephrine. Similar selectivity by verapamil or methoxy verapamil (D600) has been noted in dog coronary[28] and in rat aorta.[29] Nifedipine has also been shown to be more potent against potassium than phenylephrine or serotonin in dog femoral arteries.[30] Therefore, verapamil and nifedipine have very different constrictor selectivities and the present classification of these drugs into a single class appears to be inadequate. In contrast with the calcium antagonists, the dilator action of glyceryl trinitrate was relatively nonselective of the constrictor agents consistent with an intracellular mechanism attributed to the formation of active, unstable, intermediate s-nitrosothiols.[31]

These studies emphasize that the success of using slow calcium-channel blockers to treat coronary vasospasm will depend to some extent on the nature of the constrictor stimulus. For example, verapamil would appear most useful against serotonin-induced constriction but would be much less effective against noradrenaline and almost inactive, perhaps, against thromboxane A_2. However, the studies in vivo suggest that there are other important differences between nifedipine and verapamil. We chose to administer both calcium antagonists at a dose to bring the plasma levels into a range that would be found therapeutically. For verapamil, this is 15 to 100 ng/ml.[10,32] Verapamil (50 and 150 ng/ml) was comparable to nifedipine (15 and 45 ng/ml) with regard to the antagonism of the serotonin constrictor response in the perfused coronary artery. However, verapamil appeared to be much more effective than nifedipine in depressing the sinoatrial node, abolishing reflex tachycardia, and lengthening the atrioventricular conduction time. These experiments, performed under barbiturate anesthesia, may have potentiated the effects of verapamil on nodal tissue. Nevertheless, a marked difference between the 2 calcium antagonists was observed. It is difficult to predict what degree of large coronary artery constriction would be required to trigger an episode of vasospasm in patients. It is equally hazardous to suggest from these experiments what degree of blockade is necessary for the calcium antagonists to be effective in vasospasm. What is clear, however, is that the actions of calcium antagonists are not confined to the large coronary artery at concentrations that are effective in reducing serotonin-induced constriction. Perhaps other actions of the drugs related to a decrease in myocardial oxygen consumption are just as important in the treatment of variant angina as in angina of effort.

The Isolated Human Epicardial Coronary Artery

ROBERT GINSBURG, MD

Ring segments from coronary arteries from recipient hearts of patients receiving cardiac transplants were prepared and mounted in an organ bath. Spontaneous contractile activity, factors that affect basal tone, agonist-induced contractile responses, regional receptor distribution, activity of cardioactive drugs, and species differences were studied. Agents that mediate contraction include histamine, acetylcholine, norepinephrine, potassium and some prostaglandins. Calcium-entry blockers, nitrates and beta-adrenergic agonists caused relaxation. Major species differences exist in coronary vascular pharmacology. Ring segments from human epicardial coronary arteries are suitable for pharmacologic studies, and because of species differences, they offer an ideal model for investigating the pharmacology of the human coronary circulation.

For several years we have conducted clinical investigations of the pathogenesis, diagnosis and treatment of coronary artery spasm.[1–6] These and other studies suggest that the human epicardial coronary artery is not just a passive conduit through which blood flows, but a highly dynamic, reactive vascular structure that is subject to functional alterations by a variety of influences. To investigate the pathophysiologic mechanisms of spasm, we studied the pharmacology of human coronary vascular smooth muscle using isolated ring segments of human coronary arteries derived from both normal and diseased hearts. Although these types of in vitro studies provide interesting and useful data, extrapolation to intact systems must be made with caution, because these studies focus on only a single aspect of the many variables that exist in vivo. Nevertheless, we believe these techniques help to elucidate both pharmacologic mechanisms involved in human coronary arterial smooth muscle contraction and the pathophysiologic processes involved in coronary artery spasm.

General Methods

The cardiac transplant program at Stanford Medical Center provides us with the coronary arteries from normal and diseased hearts. We have performed pharmacologic studies on >1,000 coronary artery segments from 43 human hearts.

From the Division of Cardiology, Stanford University Medical Center, Stanford, California.

Address for reprints: Robert Ginsburg, MD, Division of Cardiology, Stanford University Medical Center, Stanford, California 94305.

The human coronary arteries were studied using a specially designed 12-chamber muscle bath and classic pharmacologic techniques. The right, left and circumflex epicardial coronary arteries were removed from the heart, cleaned of all adherent fat and connective tissue, and sectioned into 5-mm ring segments. The segments were mounted and placed under 1.2 g of tension. Equilibration time was 60 to 90 minutes. The physiologic solution was standard Tyrode's solution, except that the calcium concentration was slightly lower—2 m*M* calcium chloride. This yielded an ionized calcium measured by ion-specific electrode of 1.26 m*M*, which is similar to that of human serum. The bath was kept at 36°C, pH 7.40 to 7.45, and each bath was aerated with 95% oxygen and 5% carbon dioxide.

The coronary arteries were obtained immediately upon removal of the recipient heart from the transplant patient. Bovine, porcine and canine coronary arteries were also studied in an attempt to characterize species differences; this material was obtained from other laboratories or from slaughterhouses.

Basic Pharmacologic Characteristics of Human Coronary Artery

Basal tone: We define basal tone as the tension generated by the resting coronary segment. Human coronary ring segments exhibit basal tone, and this tone is calcium-dependent. This is found in innervated as well as denervated coronary arteries. Tone is also found in atherosclerotic ring segments; only in severely diseased segments with marked calcification is tone not consistently found.

TABLE I Effect of Drugs on In Vitro Human Coronary Artery Ring Segments

Contraction	Relaxation
Histamine (H_1)	Nitroglycerin
Norepinephrine	Diltiazem
Phenylephrine	D-600
Carbachol	Verapamil
Calcium	Nifedipine
Potassium	PGI_2 ($<10^{-6}M$)
TEA	Histamine (H_2)
Ergonovine	Isoproterenol
Serotonin	Sodium azide
$PGF_{2\alpha}$	
PGE_1	
PGE_2	
PCH_2	
PGI_2 ($>10^{-6}M$)	
Indomethacin	

Inhibition of specific receptors with adrenergic, histaminic or muscarinic blocking agents does not affect basal tone. Of the endogenous vasoactive substances that act through a receptor mechanism, prostaglandins appear to be the only class of compounds that influence basal tones. Prostacyclin, which is a potent relaxer of coronary arteries, is produced by the endothelial cells of the artery.[7] The addition to the bath of prostaglandin synthetase inhibitors, such as indomethacin or ibuprofen, causes contraction of the coronary segment from its basal state, probably by inhibiting the synthesis of prostacyclin production. The importance of prostaglandins in regulating tone has been shown in bovine coronaries,[8] and we have demonstrated similar findings in human tissue (Table I).

"Transient" contractile responses of isolated vascular smooth muscle to norepinephrine correlated well with basal tone have recently been proposed by Bevan.[9] If there is such a correlation, then the human coronary artery is another example, because transient contractile responses are seen in response to norepinephrine. These transient responses are due to the release of "intracellular" calcium stores, but whether this mechanism is crucial for the regulation of tone is unknown.

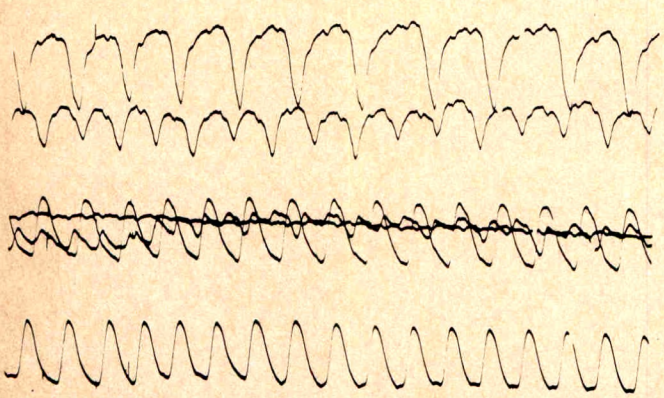

FIGURE 1. Simultaneous recording of 6 human coronary ring segments. Five of 6 segments show rhythmic periods of contraction and relaxation.

Spontaneous and induced phasic, rhythmic myogenic activity: Human coronary ring segments demonstrate spontaneous, rhythmic periods of contraction and relaxation.[10] This rhythmic activity has been described in veins and arteries from a variety of vascular beds and animal species.[11] Although a fascinating phenomenon, the physiologic role of such spontaneous activity is unknown (Fig. 1).

In human coronary arteries, this cyclic activity is usually very uniform, with cycle lengths of 60 to 80 seconds. Various agonists can induce the rhythm and change amplitude and cycle length. Not all segments have spontaneous rhythmicity, and there is no 1 characteristic that identifies which arteries will or will not demonstrate this type of activity.

Phasic, rhythmic contraction has been observed in human coronary segments from any of the 3 major arteries. This phenomenon must induce synchronous contraction of many cells of the ring segment and thus demonstrates single-unit organization in vascular smooth muscle. For this synchronization to occur, some type of communication system is needed. Electron micrographs have revealed nexuses or gap-junctions between smooth muscle cells. These have been described in other types of vascular smooth muscle cells and are thought to be the pathway for electrical activity.[12]

Electrophysiologic studies imply that action potentials generated from a pacemaker focus are propagated along the coronary segment through these nexuses, which permit synchronization of electrical and mechanical activities.

Rhythmic activity is affected by environmental factors and various vasoactive substances. Changing the bathing fluid to a more alkaline state increases cyclic amplitude, but not frequency. An acid pH causes cessation of all activity. Cold and hypoxia also cause decreased rhythmic activity. Vasoactive substances that induce activity in quiescent ring segments include norepinephrine, acetylcholine, histamine, prostaglandin-E_2 (PGE_2) (in high doses), ergonovine and potassium. Nitroglycerin, lidocaine, D-600 and diltiazem cause cessation of rhythmic activity. Thus, rhythmic activity can be regulated and controlled through the interaction of many variables.

Previous neural innervation is not necessary for rhythmic activity, because there is no difference between denervated or innervated ring segments. Rhythmic activity is not affected by alpha- or beta-adrenergic, muscarinic or histaminic-blocking agents. This spontaneous rhythmicity occurs in normal or diseased coronary arteries, but the cyclic pattern and frequency in atherosclerotic segments is usually quite irregular. This may be the result of a degenerative process involving the nexuses.

The functional importance of action potentials, pacemaker foci, conduction pathways and the resulting rhythmic activity is unknown. However, we do know that any segment of a coronary artery can exhibit this activity and secondarily generate large forces of contraction. It is interesting to speculate that the clinical phenomenon of focal spasm might involve a triggering

of electromechanical activity through the voltage-sensitive pathway.

Agonist-induced vascular smooth muscle contraction: Brodie et al[13] originally separated agonist-mediated contractile responses into 2 types, one operating at a faster rate than the other. Subsequently, Bohr[14] demonstrated that the dual effects of calcium on membrane excitation and its coupling to contraction could be seen in a single contractile response to an agonist. He separated the epinephrine-induced contraction into 2 components, a phasic or fast component and a tonic or slow component. Sitrin and Bohr[15] later demonstrated that the fast component used cellular bound calcium and that the rate-limiting factor for the release of this bound calcium was the excitability of the cell membrane.[15] These investigators and others[16] showed that the slow component was dependent upon extracellular calcium, in that this part of the response was readily inhibited in a calcium-free solution and was increased as the concentration of calcium was raised toward physiologic levels. The slow component of the norepinephrine response was also accompanied by an increase in calcium-45 uptake.

The human coronary artery responds to stimulation by an agonist with a similar biphasic response. This biphasic response has been studied in detail in the rabbit aorta and rabbit ear artery. The initial rapid phase of contraction is believed to be partially due to the release of tightly bound or "intracellular" calcium. Whether this "intracellular" calcium comes from sites located in sinks on the inner surface of the plasma membrane, from the sarcoplasmic reticulum, or from the mitochondria is not known. The slow, tonic phase of contraction, the other portion of the biphasic response, is believed to be a result mainly of the influx of freely exchangeable or extracellular calcium through the calcium "slow channels" located in the cell membrane.

The biphasic response is found only in certain vascular beds.[17–19] It has been quite a consistent observation in our coronary artery studies and probably reflects differences in calcium stores and mechanisms for release compared with other vascular tissue. The initial phasic response by the human coronary ring segment is a rapid contraction (Fig. 2) and can, depending on the agonist, account for 70% of the overall maximal tension generated. If the same response is elicited in a calcium-free solution, it can generate up to 20 to 50% of the maximal tension produced by the segment in a "normal" (1.26 m*M*) calcium solution. This suggests that the release of intracellular calcium contributes significantly to overall contraction of human coronary vascular smooth muscle.

The characteristics of the slow, tonic phase in human coronary arteries are similar to those in other animal models. This phase is presumably due to the influx of "extracellular" freely exchangeable calcium. In our studies in calcium-free solutions, no tonic response can be observed during an agonist challenge (Fig. 3).

Species differences: We compared the characteristics of coronary arteries from the dog, pig and cow using the same techniques as those used for man. Dose-response curves to a variety of agonists were compared, receptor distribution was analyzed, and basal tone and rhythmic vasoactivity were evaluated.

Our results have shown a marked variation in sensitivity of the contractile response to various agonists among animal models. No animal has all the features found in man. These differences have been quite impressive and suggest that care should be taken when selecting a species for study in an in vitro setting. Whether these differences are present in the intact animal model is not known.

In the canine coronary artery, Van Breemen et al[20] showed that in response to norepinephrine there is only

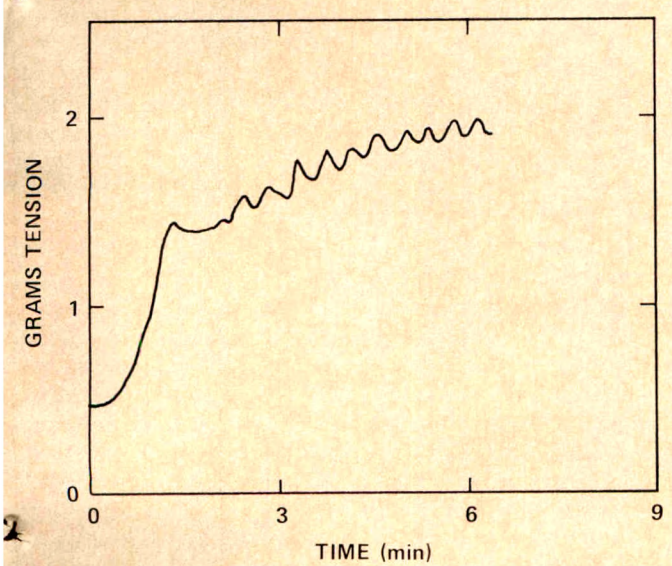

FIGURE 2. Contraction pattern of single human coronary artery ring segment to a receptor-mediated vasoactive agent, histamine. There is a rapid rate of contraction initially, and then a slower, tonic phase of contraction over several minutes.

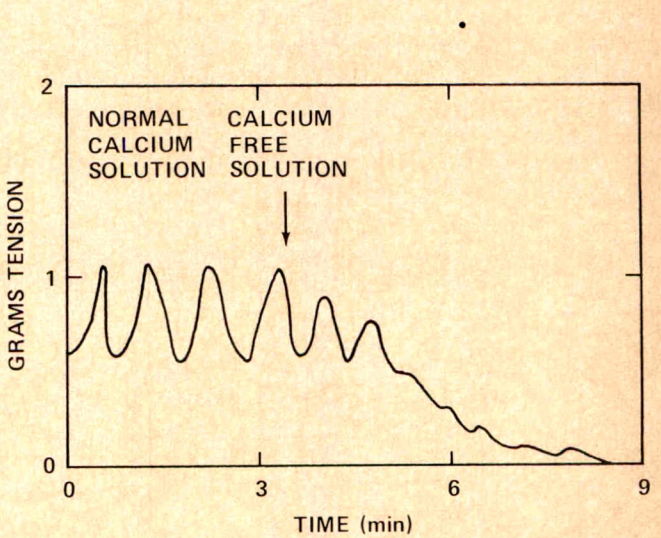

FIGURE 3. Contraction pattern of single human coronary artery ring segment in a normal and 0-calcium environment. Basal tone decreases with the removal of calcium.

an influx of extracellular calcium and no release of intracellular calcium. This is in contradistinction to the rabbit, pig or human coronary artery, which use both pools in response to norepinephrine stimulation.

Norepinephrine: The exposure of the human coronary artery ring segment to phenylephrine or norepinephrine in the presence of propranolol results in contraction of the segment. The maximal grams of tension that a segment generates in response to these drugs is usually less than to other agonists we have studied. However, the sensitivity to these drugs (median effective dose $10^{-7}M$) is similar to that found in other animal species. Unlike the canine coronary artery, the human coronary artery mobilizes 2 pools of calcium for contraction upon exposure to norepinephrine. There is both the influx of extracellular calcium and the release of intracellular calcium. The canine coronary artery uses only extracellular calcium.[20]

The contribution of the adrenergic nervous system to coronary vasoregulation has been intensively investigated. Studies in the intact dog have shown that coronary blood flow can be influenced markedly by stimulation or blockade of the alpha-adrenergic receptors that supply the large coronary arteries. Therefore, much emphasis has been placed on the neurogenic influence on the coronary circulation.[21]

Recently, Ricci et al[22] described altered adrenergic activity in patients with coronary spasm. They demonstrated that phentolamine could reverse coronary spasm and decrease coronary vascular resistance. The mechanism of action of phentolamine, however, is not completely known. Although it is an alpha-antagonist in vitro, it may have direct smooth muscle effects. Studies with long-acting alpha blockers such as phenoxybenzamine have not demonstrated uniform effectiveness in the treatment of spasm, and therefore, the role of the adrenergic system in mediating coronary spasm is questionable.

Thus, although sympathetic nerves, norepinephrine and alpha-adrenergic stimulation may play a role in the contraction of the human coronary artery, data from muscle bath studies suggest that this is not the only mechanism, nor is it the most important, either in normal physiologic processes or in pathophysiologic states such as vasospasm.

Acetylcholine: In the human coronary ring segment, acetylcholine stimulation results in contraction. Its potency lies between norepinephrine and histamine. Receptor population also changes along the length of the vessel. Of interest is the marked variability in animal models; the dog has essentially no response to acetylcholine.

Methacholine has been used in human studies to provoke coronary spasm.[23] It may operate by the indirect stimulation of the sympathetic nervous system, provoking spasm through alpha-adrenergic receptors. In vitro, this mechanism is not necessary because acetylcholine itself causes contraction of the coronary segment. Acetylcholine or carbachol is operating through a specific membrane receptor.

Histamine: The sympathetic nerves, cardiac muscle and coronary arteries are rich in mast cells and histamine. Histamine is released into the circulation during sudden withdrawal of sympathetic tone and after direct stimulation of sympathetic nerves and spinal nerve roots.[24] Therefore, it has a regulatory role in adrenergic neurotransmission. Histamine, along with acetylcholine, angiotensin, prostaglandins and norepinephrine, can alter the neurotransmitter by acting on sympathetic nerve endings. In the tissue bath, histamine can cause a potentiation of norepinephrine effects in vascular smooth muscle.[25] Thus, histamine may play a role in coronary vasoregulation.

In human coronary segments histamine is not very potent (median effective dose $1 \times 10^{-5}M$), but it does generate 1 of the greatest contractile responses in terms of grams of tension of the agonists studied. As reported previously,[26] this contraction is mediated by an H_1 receptor subtype. Also of interest is that histamine always induces rhythmic, myogenic activity. Receptor distribution analysis has demonstrated more H_1 receptors proximally than distally along the length of the artery.

Prostaglandins: Prostaglandins have been studied in in vitro preparations, including human coronary arteries.[7] Our data indicate that prostaglandins are significant mediators of basal tone.

As has been shown previously, PGE_1, PGE_2 and $PGF_{2\alpha}$ can cause contraction of the human coronary artery. PGI_2, however, is usually classified as a potent coronary smooth muscle relaxant. In the human coronary segment, PGI_2 gives a biphasic response. At low doses, it is a potent relaxer, but at higher concentrations ($>10^{-6}M$), PGI_2 produces a contractile response that is similar to that of all other vasoconstrictors studied. Therefore, a prostaglandin known to be produced in the vessel wall of the human coronary artery can cause contraction or relaxation.

Prostaglandins are formed by the enzymatic oxygenation of certain polyunsaturated fatty acids. Released prostaglandin precursor (such as arachidonic acid) is acted upon by cyclooxygenase, resulting in the formation of the cyclic endoperoxide PGH_2). In the rabbit aorta and in porcine and human coronary arteries, PGH_2 is a potent vasoconstrictor, and acts primarily on the intracellular calcium pool. In the bovine coronary artery, PGH_2 causes relaxation,[27] emphasizing that species differences do exist and that generalizations cannot be made about human pharmacology strictly from animal experiments.

Ergonovine: Although not an endogenously produced substance, ergonovine most consistently provokes coronary spasm clinically. Although ergonovine and other ergot alkaloids are known stimulators of smooth muscle contractions,[28] they have not been intensively investigated in coronary artery smooth muscle. Studies in the human coronary artery show that ergonovine operates partially through an alpha membrane receptor. Rabbit studies indicate that ergonovine operates more specifically through a serotonin-type receptor. Although ergonovine constricts the human coronary artery, the maximal grams of tension generated is the least of all agonists studied to date. Its action in vivo especially in provoking coronary spasm may not be a result of direct

stimulation of a specific receptor, but may be indirect through the release of other mediators. Understanding the pharmacologic mechanism of action of ergonovine may elucidate the pathophysiology of spasm.

Calcium-entry blockers: Fleckenstein[29] and others have examined the pharmacology of calcium blockers in vascular smooth muscle. The calcium blockers are clinically important in the treatment of arrhythmias, coronary spasm, exertional angina pectoris and cardiomyopathies.

The human coronary artery has at least 2 operational membrane calcium channels. One is a voltage-sensitive pathway and the other is a receptor-operated channel. The voltage-sensitive pathway can be activated by depolarization with high potassium. This voltage-sensitive pathway is exquisitely sensitive to calcium-entry blockers such as D-600, diltiazem, nifedipine and verapamil. Administration of these blockers eliminates basal tone and myogenic rhythmicity—physiologic phenomena operating through the voltage-sensitive pathway. The receptor-operated pathway is blocked by calcium antagonists only at high concentrations, when their activity is probably "nonspecific" in nature. Also, the release of intracellular calcium is not inhibited by these channel blockers. The observation that calcium blockers affect only the voltage-sensitive pathway is an important clue in understanding the mechanisms of spasm.

Some calcium-entry blockers exhibit selectivity in the human heart by blocking calcium entry in the coronary artery more than in the myocardium. Diltiazem is 10-fold more sensitive on the coronary bed than on cardiac muscle. D-600, nifedipine and verapamil are not selective, and block calcium entry at equimolar concentrations in the coronary arteries as well as the myocardium. This difference has clinical significance when using these agents in patients with left ventricular dysfunction.

In the human coronary artery, calcium-entry blockers eliminate basal tone. They also cause relaxation of segments that are contracted by potassium or their vasoactive agents. Relaxation is a slow process, but at high doses these blockers cause complete relaxation of the segments. It appears that these blocking agents are operating solely through the voltage-sensitive pathway.

Nitroglycerin: Although nitrates have been used clinically for >100 years, their mechanism of action is not fully understood. In the human coronary segment, nitroglycerin causes immediate relaxation of the segments. This relaxation is only 20 to 40% of that achieved by calcium-entry blockers, although it occurs more rapidly. The responses of nitrates and calcium-entry blockers are additive in the muscle bath; this is seen clinically in patients taking these drugs.

Nitrates are not calcium-entry blockers, and are in a different pharmacologic class. Nitrates act intracellularly and appear to remove or inactivate a portion of calcium used in contraction. Whether this involves cyclic guanosine monophosphate is not clear. Further research is still needed.

Atherosclerosis: Coronary artery spasm usually occurs in areas of atherosclerosis. Recent studies of dog coronary arteries have shown that cholesterol sensitizes coronary vascular smooth muscle to the effects of external calcium by a nonadrenergic mechanism.[30] Thus, it is postulated that cholesterol may alter the contractile properties of the muscle or the cell membrane. Rabbits fed high-cholesterol diets have increased sensitivity to ergonovine and serotonin, but not to norepinephrines. These animal studies and clinical studies have suggested altered pharmacology in areas of atherosclerosis.

In our studies on human coronary segments, there was increased sensitivity to histamine in atherosclerotic compared with normal segments. There was no change in sensitivity to carbachol, calcium or norepinephrine. Thus, atherosclerosis apparently can affect membrane receptors, and increased sensitivity on up-regulation can occur to specific vasoactive agonists. The role for this supersensitivity in the pathophysiology of coronary spasm is being investigated.

In summary, the human coronary artery studied in vitro has enabled us to characterize responses to a variety of agonists, examine contractile responses, identify receptor subtypes and distribution, and delineate species differences. Whether these observations have direct correlates in the in vivo setting is unknown, but these types of pharmacologic studies allow us to study a single organ in detail without the influence of local mediators or blood-borne agents. Our studies have characterized the responses to endogenous vasoactive agents and other cardioactive drugs, such as calcium-entry blockers. Two operational calcium membrane channels have been identified, as well as the functional calcium pools used in contraction. These studies may help elucidate the pathophysiology of coronary artery spasm and vascular supersensitivity in areas of atherosclerosis.

Clinical Studies of Patients With Coronary Spasm

S. BENEDICT FREEDMAN, MB, PhD, FRACP, DAVID R. RICHMOND, MB MSC, FRACP, and DAVID T. KELLY, MB, FRACP

Coronary artery spasm may cause myocardial ischemia in patients without severe coronary atherosclerotic obstruction. Spontaneous rest angina, particularly at night, is the predominant symptom; most patients are smokers. Ergonovine tests have high sensitivity and specificity for the diagnosis of coronary spasm, but should be used when vasospasm is suspected but no electrocardiogram was recorded during spontaneous angina. Arterial constriction measured during ergonovine testing suggests that the arterial hypersensitivity to vasoconstrictors at sites of atherosclerotic lesions is independent of the severity of the lesion. Coronary vasospasm may also be provoked by exercise, possibly through an alpha-adrenergic mechanism. Both spontaneous and exercise-induced attacks of vasospasm are prevented by calcium-antagonist drugs that remain effective during longer-term treatment. The cyclic nature of the condition is demonstrated when successful therapy is discontinued without recurrence of symptoms and may be due to alteration of arterial hypersensitivity.

Coronary artery spasm may cause angina in patients with and without severe atherosclerotic obstruction,[1,2] although another mechanism may be involved.[3,4] Patients with spasm but without severe organic stenoses are a more homogeneous group for pathophysiologic study, as in these patients ischemia is not caused by an increase in myocardial oxygen demand, but rather by reduced coronary blood flow and decreased vasomotor tone. This group forms the basis of this review.

Clinical Profile

Thirty-seven patients with angina due to spasm of arteries without severe stenoses were recently reviewed.[5] The male:female ratio was 3:1 and the mean age was 52 years. All patients had typical anginal pain at rest; in 86%, the pain was nocturnal. Forty-six percent had pain on exertion. Eighty-six percent were smokers, with an average tobacco consumption of 30 cigarettes/day. In 43%, there was a history of hypertension; 22% had a history of Raynaud's phenomenon and 27% had migraine headaches.

Electrocardiographic and Angiographic Findings

The electrocardiogram in the absence of pain was abnormal in 59%, showing ST- and T-wave changes.[5] ST-segment elevation was the usual finding during spontaneous angina, although ST-segment depression was occasionally seen. Major arrhythmias during angina were documented in 27% of patients. Ventricular tachycardia or fibrillation was recorded in 24% and complete atrioventricular block in 5% (1 patient had both). The arrhythmia resulted in syncope in 19% and emphasizes that vasospasm without severe coronary disease may be lethal. Coronary angiography usually revealed minor degrees of coronary artery disease. Stenoses of 30 to 50% luminal diameter narrowing were present in 86% of the patients. The coronary artery most frequently involved by spasm was the left anterior descending, which differs from the preponderance of right coronary spasm reported in 2 other series.[6,7] Occasionally, spasm involved both arteries either simultaneously[8] or separately on different occasions.[9]

Diagnosis: Ergonovine Testing

Spontaneous coronary spasm occurs infrequently during routine angiography,[10] so methods for reliably provoking spasm have been sought. Ergonovine maleate (ergometrine) has become the most widely used drug for this purpose and is given either at the time of angiography,[11] or in the coronary care unit with 12-lead elec-

trocardiography or thallium-201 myocardial scintigraphy to detect the ischemia resulting from spasm.[8,12]

Protocols for ergonovine administration differ principally in the total dose administered and the interval between successive doses. We used a starting dose of 0.05 mg, and gave incremental doses every 3 to 5 minutes to a maximum of 0.65 mg.[8] Provoked spasm is usually reversible with sublingual nitroglycerin,[8] but parenteral preparations of nitrate or nitroprusside must be available and used promptly if there is any delay in the relief of spasm.[8] Cardiopulmonary resuscitation facilities should be available.

In a study of 69 patients with chest pain and no severe coronary atherosclerosis, all 5 patients with documented variant angina had a positive ergonovine test, suggesting a high sensitivity of the test.[8] The overall sensitivity in 47 similar patients pooled from 5 series was 91%.[11,13–16] The specificity of the test is also high: In 34 patients with chest pain atypical for myocardial ischemia, no spasm was provoked by ergonovine.[8] When these figures were pooled with the results from 3 other studies,[11,15,16] the incidence of false-positive test results in 173 similar patients was only 3%, confirming the high specificity.

Serious complications of ergonovine testing have been reported recently[16–18] and suggest that ergonovine should not be given to patients with documented variant angina, but restricted to patients with suspected vasospastic angina, without electrocardiographic confirmation during chest pain.[8,16] Prolonged ambulatory recording of 2 or 3 ECG leads may detect ischemic ST-segment changes during spontaneous chest pain. If ST-segment changes are not identified by Holter monitoring, ergonovine testing is indicated and will have positive results in 40 to 53% of these patients.

Pathophysiology of Coronary Spasm

Coronary spasm may be caused by an abnormal vasoconstrictor stimulus (either exaggerated physiologic or pathologic), or arterial hypersensitivity to physiologic vasoconstriction. Both mechanisms may also occur simultaneously. Ergonovine testing suggests that increased arterial sensitivity may cause spasm. When doses as high as 0.65 mg are given to normal subjects, mild vasoconstriction of 15 to 20% results, with no localized spasm.[13,19–21] In contrast, patients with documented variant angina have severe spasm at lower ergonovine doses,[8] suggesting they have increased arterial sensitivity to ergonovine. This arterial hypersensitivity is apparently nonspecific and occurs with many vasoconstrictors: methacholine,[22–24] alkalosis from hyperventilation or TRIS buffer infusion or both,[25–27] the cold-pressor test,[28] adrenaline with and without propranolol[22,29,30] and histamine.[31] A number of observations suggest that this hypersensitivity is localized to 1 coronary artery, usually at the site of coronary atherosclerosis.

Electrocardiographic changes usually recur in the same leads during repeated attacks of vasospasm in the same patient, implying that the same artery is usually involved.[32] Both ergonovine-induced and spontaneous spasm usually occur at the same site in the same patient.[11,33,34] The majority of cases of spontaneous or ergonovine-induced spasm occur at atherosclerotic lesion sites.[35] In patients with variant angina and a positive ergonovine test finding, the lesion itself and not the whole coronary arterial tree appears to be hypersensitive to ergonovine[13,19] or alpha-adrenergic stimulation.[30] Vasoconstriction at stenosis sites is greater in patients with clinical variant angina and positive ergonovine tests than in patients with chest pain atypical for myocardial ischemia and negative ergonovine tests (Fig. 1).[19]

MacAlpin[2] postulated that local arterial hypersensitivity results from normal vasoconstriction, amplified when the luminal cross section is already reduced by a lesion.[2] If a lesion is represented as a circumferential stenosis, and assuming that vasoconstriction in the normal segment is fully translated to the lesion and that the area of the vessel wall remains constant after vasoconstriction, then the vasoconstriction to be expected at a lesion site (x) may be given by the following ex-

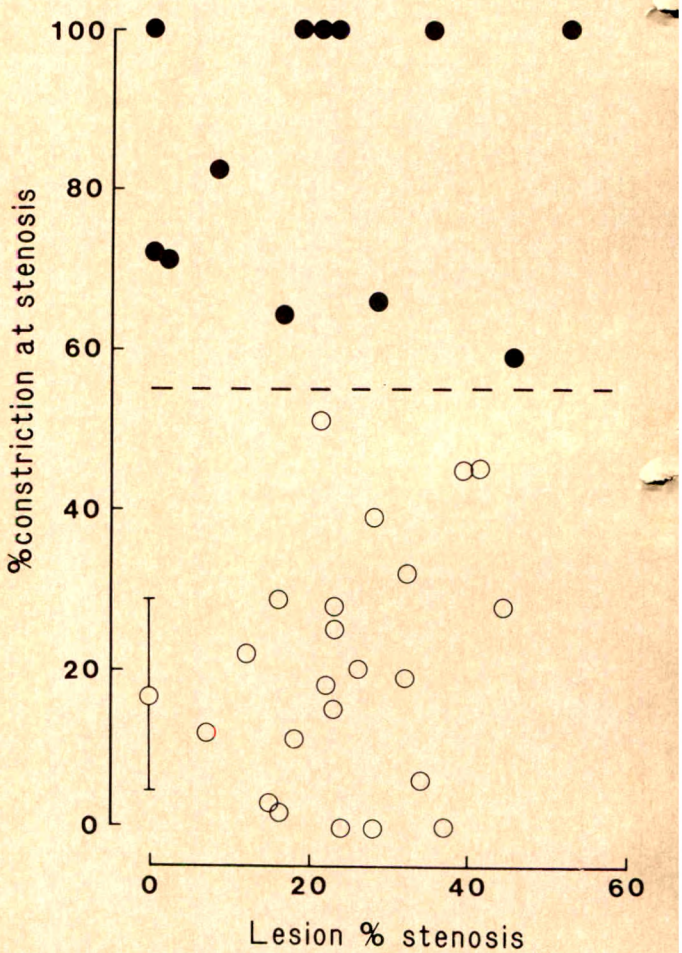

FIGURE 1. Percent constriction at a lesion site after ergonovine versus the severity of the stenosis for patients with clinical variant angina and positive ergonovine test results (**closed circles**) and patients with atypical chest pain and negative ergonovine test findings (**open circles**). The mean vasoconstriction (± standard deviation) for normal proximal arterial segments of patients with atypical chest pain is shown on the left for comparison. There was no overlap between the 2 groups of patients. **Dotted line** (55% constriction at a lesion) represents an arbitrary cut-off between negative and positive tests.

pression: $x = 100\,(1 - (1 - p/100) + (1 - y/100) - 1)/(1 - p/100)$, where p = percent stenosis of the lesion and y = percent vasoconstriction in the adjacent normal segment.[19] Using coronary angiograms before and after ergonovine administration, values could be measured for x, p and y.[19] The measured values of x were compared with values derived from equation 1 (Fig. 2). For patients with positive ergonovine tests, the observed vasoconstriction at lesion sites was always greater than that predicted by equation 1, indicating that geometric considerations alone do not explain arterial hypersensitivity at lesion sites. A similar conclusion can be drawn from the study of Brown et al,[30] which showed that lesions from patients with vasospastic angina were more sensitive to arterial vasoconstriction than lesions of similar severity from control patients.

The reason for arterial hypersensitivity at sites of atheroma is not known. Henry and Yokoyama[36] suggested that the presence of cholesterol in a lesion sensitizes the membrane to ergonovine and other constrictors, but atherosclerotic segments of human coronary arteries have been shown to be sensitive to histamine.[31] This mechanism cannot explain spasm in normal coronary arteries nor why only some atherosclerotic lesions are associated with spasm.

Exercise-Induced Coronary Spasm

Levene and Freeman in 1976[37] first suggested coronary spasm could occur during exertion. Yasue et al[38,39] demonstrated epicardial coronary artery spasm at angiography associated with ST-segment elevation during exercise; this has been confirmed by others.[40,41]

In our patients,[5] 13 of 30 (43%) with coronary artery spasm who exercised without therapy had angina and ST-segment elevation. A prevalence of 24 to 54% has been reported.[7,42,43]

Alpha-adrenergic vasoconstriction was postulated as the cause, because phenoxybenzamine suppressed the response in doses which shifted the phenylephrine dose-response curve.[37] In our own experience, 20 mg of phenoxybenzamine was effective in only 3 of 8 patients, although postural tachycardia or hypotension indicated that some alpha-adrenergic blockade had been produced. Fuller et al[44] found that 30 mg of phenoxybenzamine was ineffective in 2 patients; Yasue et al[39] reported 30 mg of phenoxybenzamine as effective in 3 of 4 patients, and phentolamine (0.2 mg/kg) effective in 6 of 9 patients.[38] The nonuniform response to alpha-blocking drugs may indicate that the degree of alpha blockade was not always sufficient to counteract the stimulus or that exercise-induced coronary spasm may be mediated by other mechanisms.

Yasue et al[39] described a diurnal variation in exercise coronary spasm. All 13 patients who exercised in the early morning had reproducible spasm, but only 2 also had spasm during exercise in the afternoon. Yasue[39,45] attributed this to a circadian rhythm of coronary artery smooth muscle tone; coronary diameters were smaller and responsiveness to nitroglycerin greater in the early morning. Although diurnal patterns were not specifically examined in our patients, all 10 who were exercised in the afternoon developed coronary spasm. One of our patients had a diurnal response to verapamil, requiring higher blood levels to prevent exercise coronary spasm in the morning than in the afternoon.[41] The difference in diurnal responses between series is not apparent.

The calcium-antagonist drugs verapamil,[41] diltiazem and nifedipine[38,39] are effective in preventing attacks of coronary artery spasm. In our own series of 13 patients, 11 were exercised again after pretreatment with oral verapamil. Verapamil alone was effective in 8 of the 11; in 3, additional nitrates were required to prevent spasm. Fuller et al[44] also described 2 patients in whom verapamil was ineffective, whereas isosorbide prevented exercise spasm. The dosage of drug is important to prevent exercise spasm. The results from 3 patients with

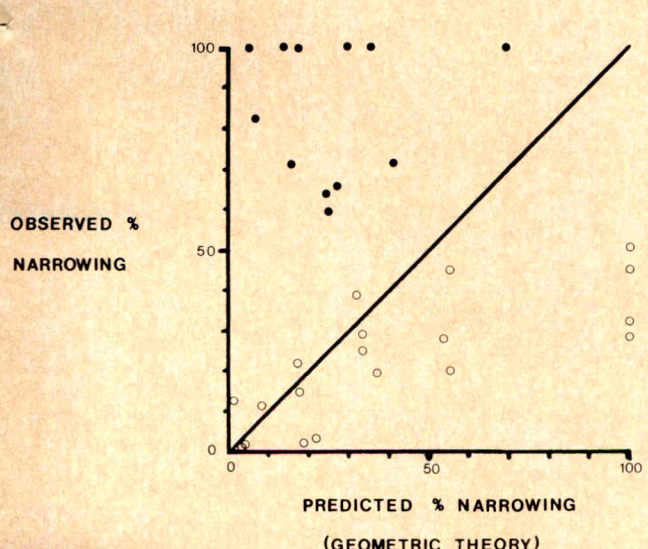

FIGURE 2. Predicted percent narrowing versus observed percent narrowing at lesion sites in patients with positive (**closed circles**) and negative (**open circles**) ergonovine tests. The line represents identity between observed and predicted values. Observed values from patients with a negative test fell on or below the line, while values from patients with a positive test were all above the line.

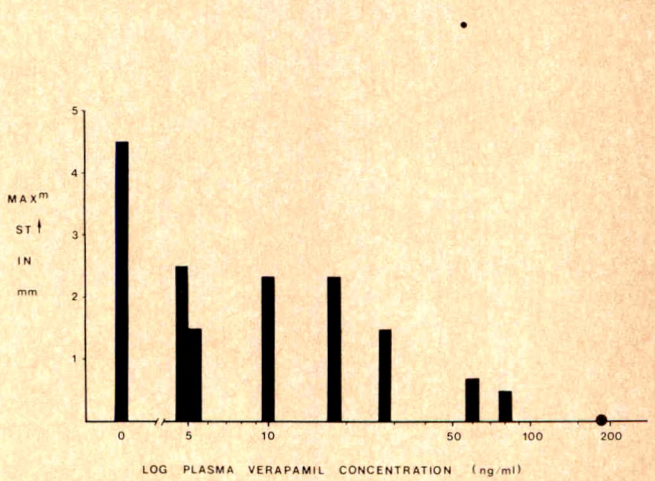

FIGURE 3. Maximal degree of ST-segment elevation (**vertical bars**) during repeated exercise tests versus plasma verapamil concentration in patients with reproducible exercise-induced coronary spasm. With increasing concentrations of verapamil, there was progressively less ST-segment elevation, and the test was negative (**circle**) at a concentration of 191 ng/ml.

reproducible exercise-induced spasm treated with different doses of verapamil are shown in Figure 3. The height of the vertical bars, representing the maximal amount of ST-segment elevation during exercise, shows a progressive decrease with increasing plasma concentrations of verapamil, until the test is completely negative at a plasma concentration of 191 mg/ml (circle). The range of verapamil plasma concentrations required to inhibit exercise spasm in these patients is within the range of plasma concentrations achieved by dosage with 320 mg/day (80 mg every 6 hours).[41,46,47] Spontaneous angina was also prevented by the same mean dose of verapamil in a larger group of patients,[5] indicating that therapeutic levels of verapamil are probably similar for both exercise-induced and spontaneous coronary spasm.

Medical Therapy for Coronary Spasm

Nitrates are usually effective in relieving acute attacks of spasm, but are ineffective for prophylaxis.

All calcium-antagonist drugs are effective in preventing coronary artery spasm.[5,48] Nifedipine, verapamil and diltiazem are equally effective if used in appropriate dosage.[49–53] Long-term verapamil alone or with isosorbide dinitrate has been very useful for the prevention of coronary spasm.[5] Of 37 patients, 32 became asymptomatic or satisfactorily controlled, and 3 of the remaining 5 achieved control by substitution of nifedipine for verapamil. The symptomatic response was maintained during a follow-up for a mean of 21 months. The mean dosage of verapamil was 320 mg/day and of nifedipine was 60 mg/day. No patient had myocardial infarction or died during the follow-up study.

In some patients, successful long-term medical therapy can be withdrawn without recurrence of angina.[5] In such patients, ergonovine tests, using the same or higher doses as had previously provoked spasm, were no longer positive.[54] This implies that the arterial hypersensitivity to ergonovine previously demonstrated was no longer present.

Clinical Implications

Coronary artery spasm may cause myocardial ischemia both at rest and during exertion, and should be suspected in patients with typical anginal symptoms at night or in the early morning. The underlying cause appears to be coronary arterial hypersensitivity to a number of vasoconstrictors at sites of minor atherosclerosis. Treatment should be directed toward preventing arterial smooth muscle constriction. The calcium-antagonist drugs are clinically effective in preventing episodes of coronary spasm.
